Preface

The methods of organic synthesis have continued to advance rapidly and we have made an effort to reflect those advances in this Fifth Edition. Among the broad areas that have seen major developments are enantioselective reactions and transition metal catalysis. Computational chemistry is having an expanding impact on synthetic chemistry by evaluating the energy profiles of mechanisms and providing structural representation of unobservable intermediates and transition states.

The organization of Part B is similar to that in the earlier editions, but a few changes have been made. The section on introduction and removal of protecting groups has been moved forward to Chapter 3 to facilitate consideration of protecting groups throughout the remainder of the text. Enolate conjugate addition has been moved from Chapter 1 to Chapter 2, where it follows the discussion of the generalized aldol reaction. Several new sections have been added, including one on hydroalumination, carboalumination, and hydrozirconation in Chapter 4, another on the olefin metathesis reactions in Chapter 8, and an expanded discussion of the carbonyl-ene reaction in Chapter 10.

Chapters 1 and 2 focus on enolates and other carbon nucleophiles in synthesis. Chapter 1 discusses enolate formation and alkylation. Chapter 2 broadens the discussion to other carbon nucleophiles in the context of the generalized aldol reaction, which includes the Wittig, Peterson, and Julia olefination reactions. The chapter and considers the stereochemistry of the aldol reaction in some detail, including the use of chiral auxiliaries and enantioselective catalysts.

Chapters 3 to 5 focus on some fundamental functional group modification reactions. Chapter 3 discusses common functional group interconversions, including nucleophilic substitution, ester and amide formation, and protecting group manipulations. Chapter 4 deals with electrophilic additions to double bonds, including the use of hydroboration to introduce functional groups. Chapter 5 considers reductions by hydrogenation, hydride donors, hydrogen atom donors, and metals and metal ions.

Chapter 6 looks at concerted pericyclic reactions, including the Diels-Alder reaction, 1,3-dipolar cycloaddition, [3,3]- and [2,3]-sigmatropic rearrangements, and thermal elimination reactions. The carbon-carbon bond-forming reactions are emphasized and the stereoselectivity of the reactions is discussed in detail.

Chapters 7 to 9 deal with organometallic reagents and catalysts. Chapter 7 considers Grignard and organolithium reagents. The discussion of organozinc reagents emphasizes their potential for enantioselective addition to aldehydes. Chapter 8 discusses reactions involving transition metals, with emphasis on copper- and palladium-mediated reactions. Chapter 9 considers the use of boranes, silanes, and stannanes in carbon-carbon bond formation. These three chapters focus on reactions such as nucleophilic addition to carbonyl groups, the Heck reaction, palladium-catalyzed cross-coupling, olefin metathesis, and allyl- boration, silation, and stannylation. These organometallic reactions currently are among the more important for construction of complex carbon structures.

Chapter 10 considers the role of reactive intermediates—carbocations, carbenes, and radicals—in synthesis. The carbocation reactions covered include the carbonyl-ene reaction, polyolefin cyclization, and carbocation rearrangements. In the carbene section, addition (cyclopropanation) and insertion reactions are emphasized. Recent development of catalysts that provide both selectivity and enantioselectivity are discussed, and both intermolecular and intramolecular (cyclization) addition reactions of radicals are dealt with. The use of atom transfer steps and tandem sequences in synthesis is also illustrated.

Chapter 11 focuses on aromatic substitution, including electrophilic aromatic substitution, reactions of diazonium ions, and palladium-catalyzed nucleophilic aromatic substitution. Chapter 12 discusses oxidation reactions and is organized on the basis of functional group transformations. Oxidants are subdivided as transition metals, oxygen and peroxides, and other oxidants.

Chapter 13 illustrates applications of synthetic methodology by multistep synthesis and perhaps provides some sense of the evolution of synthetic capabilities. Several syntheses of two relatively simple molecules, juvabione and longifolene, illustrate some classic methods for ring formation and functional group transformations and, in the case of longifolene, also illustrate the potential for identification of relatively simple starting materials by retrosynthetic analysis. The syntheses of Prelog-Djerassi lactone highlight the methods for control of multiple stereocenters, and those of the Taxol precursor Baccatin III show how synthesis of that densely functionalized tricyclic structure has been accomplished. The synthesis of epothilone A illustrates both control of acyclic stereochemistry and macrocyclization methods, including olefin metathesis. The syntheses of (+)-discodermolide have been added, illustrating several methods for acyclic stereoselectivity and demonstrating the virtues of convergency. The chapter ends with a discussion of solid phase synthesis and its application to syntheses of polypeptides and oligonucleotides, as well as in combinatorial synthesis.

There is increased emphasis throughout Part B on the representation of transition structures to clarify stereoselectivity, including representation by computational models. The current practice of organic synthesis requires a thorough knowledge of molecular architecture and an understanding of how the components of a structure can be assembled. Structures of enantioselective reagents and catalysts are provided to help students appreciate the three-dimensional aspects of the interactions that occur in reactions.

A new feature of this edition is a brief section of commentary on the reactions in most of the schemes, which may point out a specific methodology or application. Instructors who want to emphasize the broad aspects of reactions, as opposed to specific examples, may wish to advise students to concentrate on the main flow of the text, reserving the schemes and commentary for future reference. As mentioned in the

Acknowledgment and Personal Statement, the selection of material in the examples and schemes does not reflect priority, importance, or generality. It was beyond our capacity to systematically survey the many examples that exist for most reaction types, and the examples included are those that came to our attention through literature searches and reviews.

Several computational studies have been abstracted and manipulable three-dimensional images of reactants, transition structures, intermediates, and products provided. This material provides the opportunity for detailed consideration of these representations and illustrates how computational chemistry can be applied to the mechanistic and structural interpretation of reactivity. This material is available in the Digital Resource at springer.com/carey-sundberg.

As in previous editions, the problems are drawn from the literature and references are given. In this addition, brief answers to each problem have been provided and are available at the publishers website.

Acknowledgment and Personal Statement

The revision and updating of *Advanced Organic Chemistry* that appears as the Fifth Edition spanned the period September 2002 through December 2006. Each chapter was reworked and updated and some reorganization was done, as described in the Prefaces to Parts A and B. This period began at the point of conversion of library resources to electronic form. Our university library terminated paper subscriptions to the journals of the American Chemical Society and other journals that are available electronically as of the end of 2002. Shortly thereafter, an excavation mishp in an adjacent construction project led to structural damage and closure of our departmental library. It remained closed through June 2007, but thanks to the efforts of Carol Hunter, Beth Blanton-Kent, Christine Wiedman, Robert Burnett, and Wynne Stuart, I was able to maintain access to a few key print journals including the *Journal of the American Chemical Society*, *Journal of Organic Chemistry*, *Organic Letters*, *Tetrahedron*, and *Tetrahedron Letters*. These circumstances largely completed an evolution in the source for specific examples and data. In the earlier editions, these were primarily the result of direct print encounter or search of printed *Chemical Abstracts* indices. The current edition relies mainly on electronic keyword and structure searches. Neither the former nor the latter method is entirely systematic or comprehensive, so there is a considerable element of circumstance in the inclusion of specific material. There is no intent that specific examples reflect either priority of discovery or relative importance. Rather, they are interesting examples that illustrate the point in question.

Several reviewers provided many helpful corrections and suggestions, collated by Kenneth Howell and the editorial staff of Springer. Several colleagues provided invaluable contributions. Carl Trindle offered suggestions and material from his course on computational chemistry. Jim Marshall reviewed and provided helpful comments on several sections. Michal Sabat, director of the Molecular Structure Laboratory, provided a number of the graphic images. My co-author, Francis A. Carey, retired in 2000 to devote his full attention to his text, *Organic Chemistry*, but continued to provide valuable comments and insights during the preparation of this edition. Various users of prior editions have provided error lists, and, hopefully, these corrections have

been made. Shirley Fuller and Cindy Knight provided assistance with many aspects of the preparation of the manuscript.

This Fifth Edition is supplemented by the *Digital Resource* that is available through the publisher's web site. The *Topics* pursue several areas in somewhat more detail than was possible in the printed text. The *Digital Resource* summarizes the results of several computational studies and presents three-dimensional images, comments, and exercises based on the results. These were developed with financial support from the Teaching Technology Initiative of the University of Virginia. Technical support was provided by Michal Sabat, William Rourke, Jeffrey Hollier, and David Newman. Several students made major contributions to this effort. Sara Higgins Fitzgerald and Victoria Landry created the prototypes of many of the sites. Scott Geyer developed the dynamic representations using IRC computations. Tanmaya Patel created several sites and developed the measurement tool. I also gratefully acknowledge the cooperation of the original authors of these studies in making their output available.

Brief summaries of the problem solutions have been developed and are available to instructors through the publishers website.

It is my hope that the text, problems, and other material will assist new students to develop a knowledge and appreciation of structure, mechanism, reactions, and synthesis in organic chemistry. It is gratifying to know that some 200,000 students have used earlier editions, hopefully to their benefit.

Richard J. Sundberg

June 2007

Introduction

The focus of Part B is on the closely interrelated topics of *reactions* and *synthesis*. In each of the first twelve chapters, we consider a group of related reactions that have been chosen for discussion primarily on the basis of their usefulness in synthesis. For each reaction we present an outline of the mechanism, its regio- and stereochemical characteristics, and information on typical reaction conditions. For the more commonly used reactions, the schemes contain several examples, which may include examples of the reaction in relatively simple molecules and in more complex structures. The goal of these chapters is to develop a fundamental base of knowledge about organic reactions in the context of synthesis. We want to be able to answer questions such as: What transformation does a reaction achieve? What is the mechanism of the reaction? What reagents and reaction conditions are typically used? What substances can catalyze the reaction? How sensitive is the reaction to other functional groups and the steric environment? What factors control the stereoselectivity of the reaction? Under what conditions is the reaction enantioselective?

Synthesis is the application of one or more reactions to the preparation of a particular target compound, and can pertain to a single-step transformation or to a number of sequential steps. The selection of a reaction or series of reactions for a synthesis involves making a judgment about the most effective possibility among the available options. There may be a number of possibilities for the synthesis of a particular compound. For example, in the course of learning about the reactions in Chapter 1 to 12, we will encounter a number of ways of making ketones, as outlined in the scheme that follows.

The focus of Chapters 1 and 2 is enolates and related carbon nucleophiles such as silyl enol ethers, enamines, and imine anions, which can be referred to as *enolate equivalents*.

Chapter 1 deals with alkylation of carbon nucleophiles by alkyl halides and tosylates. We discuss the major factors affecting stereoselectivity in both cyclic and acyclic compounds and consider intramolecular alkylation and the use of chiral auxiliaries.

Aldol addition and related reactions of enolates and enolate equivalents are the subject of the first part of Chapter 2. These reactions provide powerful methods for controlling the stereochemistry in reactions that form hydroxyl- and methyl-substituted structures, such as those found in many antibiotics. We will see how the choice of the nucleophile, the other reagents (such as Lewis acids), and adjustment of reaction conditions can be used to control stereochemistry. We discuss the role of open, cyclic, and chelated transition structures in determining stereochemistry, and will also see how chiral auxiliaries and chiral catalysts can control the enantioselectivity of these reactions. Intramolecular aldol reactions, including the Robinson annulation are discussed. Other reactions included in Chapter 2 include Mannich, carbon acylation, and olefination reactions. The reactivity of other carbon nucleophiles including phosphonium ylides, phosphonate carbanions, sulfone anions, sulfonium ylides, and sulfoxonium ylides are also considered.

Among the olefination reactions, those of phosphonium ylides, phosphonate anions, silylmethyl anions, and sulfone anions are discussed. This chapter also includes a section on conjugate addition of carbon nucleophiles to α,β -unsaturated carbonyl compounds. The reactions in this chapter are among the most important and general of the carbon-carbon bond-forming reactions.

Chapters 3 to 5 deal mainly with introduction and interconversion of functional groups. In Chapter 3, the conversion of alcohols to halides and sulfonates and their subsequent reactions with nucleophiles are considered. Such reactions can be used to introduce functional groups, invert configuration, or cleave ethers. The main methods of interconversion of carboxylic acid derivatives, including acyl halides, anhydrides, esters, and amides, are reviewed. Chapter 4 discusses electrophilic additions to alkenes, including reactions with protic acids, oxymercuration, halogenation, sulfenylation, and selenylation. In addition to introducing functional groups, these reagents can be used to effect cyclization reactions, such as iodolactonization. The chapter also includes the fundamental hydroboration reactions and their use in the synthesis of alcohols, aldehydes, ketones, carboxylic acids, amines, and halides. Chapter 5 discusses reduction reactions at carbon-carbon multiple bonds, carbonyl groups, and certain other functional groups. The introduction of hydrogen by hydrogenation frequently establishes important stereochemical relationships. Both heterogeneous and homogeneous catalysts are discussed, including examples of enantioselective catalysts. The reduction of carbonyl groups also often has important stereochemical consequences because a new stereocenter is generated. The fundamental hydride transfer reagents NaBH_4 and LiAlH_4 and their derivatives are considered. Examples of both enantioselective reagents and catalysts are discussed, as well as synthetic applications of several other kinds of reducing agents, including hydrogen atom donors and metals.

In Chapter 6 the focus returns to carbon-carbon bond formation through cycloadditions and sigmatropic rearrangements. The Diels-Alder reaction and 1,3-dipolar cycloaddition are the most important of the former group. The predictable regiochemistry and stereochemistry of these reactions make them very valuable for ring formation. Intramolecular versions of these cycloadditions can create at least two new rings, often with excellent stereochemical control. Although not as broad in scope, $[2+2]$ cycloadditions, such as the reactions of ketenes and photocycloaddition reactions of enones, also have important synthetic applications. The $[3,3]$ - and $[2,3]$ -sigmatropic rearrangements also proceed through cyclic transition structures and usually provide predictable stereochemical control. Examples of $[3,3]$ -sigmatropic rearrangements include the Cope rearrangement of 1,5-dienes, the Claisen rearrangement of allyl vinyl ethers, and the corresponding reactions of ester enolate equivalents.

Claisen-type rearrangements of
ester enolates, ketene acetals,
and silyl ketene acetals

Synthetically valuable [2,3]-sigmatropic rearrangements include those of allyl sulfonium and ammonium ylides and α' -carbanions of allyl vinyl ethers.

This chapter also discusses several β -elimination reactions that proceed through cyclic transition structures.

In Chapters 7, 8, and 9, the focus is on organometallic reagents. Chapter 7 considers the Group I and II metals, emphasizing organolithium, -magnesium, and -zinc reagents, which can deliver saturated, unsaturated, and aromatic groups as nucleophiles. Carbonyl compounds are the most common co-reactants, but imines and nitriles are also reactive. Important features of the zinc reagents are their adaptability to enantioselective catalysis and their compatibility with many functional groups. Chapter 8 discusses the role of transition metals in organic synthesis, with the emphasis on copper and palladium. The former provides powerful nucleophiles that can react by displacement, epoxide ring opening, and conjugate addition, while organopalladium compounds are usually involved in catalytic processes. Among the important applications are allylic substitution, coupling of aryl and vinyl halides with alkenes (Heck reaction), and cross coupling with various organometallic reagents including magnesium, zinc, tin, and boron derivatives. Palladium catalysts can also effect addition of organic groups to carbon monoxide (carbonylation) to give ketones, esters, or amides. Olefin metathesis reactions, also discussed in this chapter, involve ruthenium or molybdenum catalysts

and both intermolecular and ring-closing metathesis have recently found applications in synthesis.

Chapter 9 discusses carbon-carbon bond-forming reactions of boranes, silanes, and stannanes. The borane reactions usually involve $B \rightarrow C$ migrations and can be used to synthesize alcohols, aldehydes, ketones, carboxylic acids, and amines. There are also stereoselective alkene syntheses based on organoborane intermediates. Allylic boranes and boronates provide stereospecific and enantioselective addition reactions of allylic groups to aldehydes. These reactions proceed through cyclic transition structures and provide a valuable complement to the aldol reaction for stereochemical control of acyclic systems. The most important reactions of silanes and stannanes involve vinyl and allyl derivatives. These reagents are subject to electrophilic attack, which is usually followed by demetallation, resulting in net substitution by the electrophile, with double-bond transposition in the allylic case. Both these reactions are under the regiochemical control of the β -carbocation-stabilizing ability of the silyl and stannyl groups.

In Chapter 10, the emphasis is on synthetic application of carbocations, carbenes, and radicals in synthesis. These intermediates generally have high reactivity and short lifetimes, and successful application in synthesis requires taking this factor into account. Examples of reactions involving carbocations are the carbonyl-ene reaction, polyene cyclization, and directed rearrangements and fragmentations. The unique divalent character of the carbenes and related intermediates called carbenoids can be exploited in synthesis. Both addition (cyclopropanation) and insertion are characteristic reactions. Several zinc-based reagents are excellent for cyclopropanation, and rhodium catalysts have been developed that offer a degree of selectivity between addition and insertion reactions.

Radical reactions used in synthesis include additions to double bonds, ring closure, and atom transfer reactions. Several sequences of tandem reactions have been developed that can close a series of rings, followed by introduction of a substituent. Allylic stannanes are prominent in reactions of this type.

Chapter 11 reviews aromatic substitution reactions including electrophilic aromatic substitution, substitution via diazonium ions, and metal-catalyzed nucleophilic substitution. The scope of the latter reactions has been greatly expanded in recent years by the development of various copper and palladium catalysts. Chapter 12 discusses oxidation reactions. For the most part, these reactions are used for functional group transformations. A wide variety of reagents are available and we classify them as based on metals, oxygen and peroxides, and other oxidants. Epoxidation reactions have special significance in synthesis. The introduction of the epoxide ring can set the stage for subsequent nucleophilic ring opening to introduce a new group or extend the carbon chain. The epoxidation of allylic alcohols can be done enantioselectively, so epoxidation followed by ring opening can control the configuration of three contiguous stereocenters.

The methods available for synthesis have advanced dramatically in the past half-century. Improvements have been made in selectivity of conditions, versatility of transformations, stereochemical control, and the efficiency of synthetic processes. The range of available reagents has expanded. Many reactions involve compounds of boron, silicon, sulfur, selenium, phosphorus, and tin. Catalysis, particularly by transition metal complexes, has also become a key part of organic synthesis. The mechanisms of catalytic reactions are characterized by *catalytic cycles* and require an understanding not only of the ultimate bond-forming and bond-breaking steps, but also of the mechanism for regeneration of the active catalytic species and the effect of products, by-products, and other reaction components in the catalytic cycle.

Over the past decade enantioselectivity has become a key concern in reactivity and synthesis. Use of *chiral auxiliaries* and/or *enantioselective catalysts* to control configuration is often a crucial part of synthesis. The analysis and interpretation of enantioselectivity depend on consideration of diastereomeric intermediates and transition structures on the reaction pathway. Often the differences in free energy of competing reaction pathways are on the order of 1 kcal, reflecting small and subtle differences in structure. We provide a number of examples of the structural basis for enantioselectivity, but a good deal of unpredictability remains concerning the degree of enantioselectivity. Small changes in solvent, additives, catalyst structure, etc., can make large differences in the observed enantioselectivity.

Mechanistic insight is a key to both discovery of new reactions and to their successful utilization in specific applications. Use of reactions in a synthetic context often entails optimization of reaction conditions based on mechanistic interpretations. Part A of this text provides fundamental information about the reactions discussed here. Although these mechanistic concepts may be recapitulated briefly in Part B, the details may not be included; where appropriate, reference is made to relevant sections in Part A. In addition to experimental mechanistic studies, many reactions of

synthetic interest are now within the range of computational analysis. Intermediates and transition structures on competing or alternative reaction pathways can be modeled and compared on the basis of MO and/or DFT calculations. Such computations can provide intricate structural details and may lead to mechanistic insight. A number of such studies are discussed in the course of the text.

A key skill in the practice of organic synthesis is the ability to recognize important aspects of molecular structure. Recognition of all aspects of stereochemistry, including conformation, ring geometry, and configuration are crucial to understanding reactivity and applying reactions to synthesis. We consider the stereochemical aspects of each reaction. For most reactions, good information is available on the structure of key intermediates and the transition structure. Students should make a particular effort to understand the consequences of intermediates and transition structures for reactivity.

Applying the range of reactions to synthesis involves planning and foreseeing the outcome of a particular sequence of reactions. Planning is best done on the basis of *retrosynthetic analysis*, the identification of key subunits of the target molecule that can be assembled by feasible reactions. The structure of the molecule is studied to identify bonds that are amenable to formation. For example, a molecule containing a carbon-carbon double bond might be disconnected at that bond, since there are numerous ways to form a double bond from two separate components. β -Hydroxy carbonyl units suggest the application of the aldol addition reaction, which assembles this functionality from two separate carbonyl compounds.

The construction of the overall molecular skeleton, that is, the carbon-carbon and other bonds that constitute the framework of the molecule, is the primary challenge. Molecules also typically contain a number of functional groups and they must be compatible with the projected reactivity at each step in the synthesis. This means that it may be necessary to modify or protect functional groups at certain points. Generally speaking, the protection and interconversion of functional groups is a less fundamental challenge than construction of the molecular framework because there are numerous methods for functional group interconversion.

As the reactions discussed in Chapters 1 to 12 illustrate, the methodology of organic synthesis is highly developed. There are many possible means for introduction and interconversion of functional groups and for carbon-carbon bond formation, but putting them together in a multistep synthesis requires more than knowledge of the reactions. A plan that orchestrates the sequence of reactions toward the final goal is necessary.

In Chapter 13, we discuss some of the generalizations of multistep synthesis. Retrosynthetic analysis identifies bonds that can be broken and key intermediates. Various methods of stereochemical control, including intramolecular interactions. Chiral auxiliaries, and enantioselective catalysts, can be used. Protective groups can be utilized to prevent functional group interferences. Ingenuity in synthetic planning can lead to efficient construction of molecules. We take a retrospective look at the synthesis of six molecules of differing complexity. Juvabione is an oxidized terpene

with one ring and two stereocenters. Successful syntheses date from the late 1960s to the present. Longifolene is a tricyclic sesquiterpene and its synthesis poses the problem of ring construction. The Prelog-Djerassi lactone, the lactone of (2*R*,3*S*,4*R*,6*R*)-3-hydroxy-2,4,6-trimethylheptanedioic acid, is a degradation product isolated from various antibiotics. Its alternating methyl and hydroxy groups are typical of structural features found in many antibiotics and other natural substances biosynthetically derived from polypropionate units. Its synthesis illustrates methods of acyclic stereochemical control.

Synthetic methodology is applied to molecules with important biological activity such as the prostaglandins and steroids. Generally speaking, the stereochemistry of these molecules can be controlled by relationships to the ring structure.

A somewhat more complex molecule, both in terms of the nature of the rings and the density of functionality is Baccatin III, a precursor of the antitumor agent Taxol[®]. We summarize syntheses of Baccatin III that involve sequences of 40–50 reactions. Baccatin III is a highly oxygenated diterpene and these syntheses provide examples of ring construction and functional group manipulations. Despite its complexity, the syntheses of Baccatin III, for the most part, also depend on achieving formation of rings and use of the ring structure to control stereochemistry.

Macrocyclic antibiotics such as the erythronolide present an additional challenge.

These molecules contain many stereogenic centers and they are generally constructed from acyclic segments, so the ability to control configuration in acyclic systems is necessary. Solutions to this problem developed beginning in the 1960s are based on analysis of transition structures and the concepts of cyclic transition structure and facial selectivity. The effect of nearby stereogenic centers has been studied carefully and resulted in concepts such as the Felkin model for carbonyl addition reactions and Cram's model of chelation control. In Chapter 13, several syntheses of epothilone A, a 16-membered lactone that has antitumor activity, are summarized. The syntheses illustrate methods for both acyclic stereochemical control and macrocyclization, including the application of the olefin metathesis reaction.

We also discuss the synthesis of (+)-discodermolide, a potent antitumor agent isolated from a deep-water sponge in the Caribbean Sea. The first synthesis was reported in the mid-1990s, and synthetic activity is ongoing. Discodermolide is a good example of the capability of current synthetic methodology to produce complex molecules. The molecule contains a 24-carbon chain with a single lactone ring connecting C(1) and C(5). There are eight methyl substituents and six oxygen substituents, one of which is carbamoylated. The chain ends with a diene unit. By combining and refining elements of several earlier syntheses, it was possible to carry

out a 39-step synthesis. The early stages were done on a kilogram scale and the entire effort provided 60 grams of the final product for preliminary clinical evaluation.

There is no synthetic path that is uniquely “correct,” but there may be factors that recommend particular pathways. The design of a synthesis involves applying one’s knowledge about reactions. Is the reaction applicable to the particular steric and electronic environment under consideration? Is the reaction compatible with other functional groups and structures that are present elsewhere in the molecule? Will the reaction meet the regio- and stereochemical requirements that apply? Chemists rely on mechanistic considerations and the precedent of related reactions to make these judgments. Other considerations may come into play as well, such as availability and/or cost of starting materials, and safety and environmental issues might make one reaction preferable to another. These are critical concerns in synthesis on a production scale.

Certain types of molecules, especially polypeptides and polynucleotides, lend themselves to synthesis on solid supports. In such syntheses, the starting material is attached to a small particle (bead) or a surface and the molecule remains attached during the course of the synthetic sequence. Solid phase synthesis also plays a key role in creation of combinatorial libraries, that is, collections of many molecules synthesized by a sequence of reactions in which the subunits are systematically varied to create a range of structures (*molecular diversity*).

There is a vast amount of knowledge about reactions and how to use them in synthesis. The primary source for this information is the published chemical literature that is available in numerous journals, and additional information can be found in patents, theses and dissertations, and technical reports of industrial and governmental organizations. There are several means of gaining access to information about specific reactions. The series *Organic Syntheses* provides examples of specific transformations with detailed experimental procedures. Another series, *Organic Reactions*, provides fundamental information about the scope and mechanism as well as comprehensive literature references to many examples of a specific reaction type. Various review journals, including *Accounts of Chemical Research* and *Chemical Reviews*, provide overviews of particular reactions. A traditional system of organization is based on *named reactions*. Many important reactions bear well-recognized names of the chemists involved in their discovery or development. Other names such as dehydration, epoxidation, enolate alkylation, etc., are succinct descriptions of the structural changes associated with the reaction. This vocabulary is an important tool for accessing information about organic reactions. There are large computerized databases of organic reactions, most notably those of *Chemical Abstracts* and *Beilstein*. Chemical structures can be uniquely described and these databases can be searched for complete or partial structures. Systematic ways of searching for reactions are also incorporated into the databases. Another database, *Science Citation Index*, allows search for subsequent citations of published work.

A major purpose of organic synthesis at the current time is the discovery, understanding, and application of biological activity. Pharmaceutical laboratories, research foundations, and government and academic institutions throughout the world are engaged in this research. Many new compounds are synthesized to discover useful biological activity, and when activity is discovered, related compounds are synthesized to improve it. Syntheses suitable for production of drug candidate molecules are developed. Other compounds are synthesized to explore the mechanisms of biological processes. The ultimate goal is to apply this knowledge about biological activity for treatment and prevention of disease. Another major application of synthesis is in agriculture for control of insects and weeds. Organic synthesis also plays a part in the development of many consumer products, such as fragrances.

The unique power of synthesis is the ability to create new molecules and materials with valuable properties. This capacity can be used to interact with the natural world, as in the treatment of disease or the production of food, but it can also produce compounds and materials beyond the capacity of living systems. Our present world uses vast amounts of synthetic polymers, mainly derived from petroleum by synthesis. The development of nanotechnology, which envisions the application of properties at the molecular level to catalysis, energy transfer, and information management has focused attention on multimolecular arrays and systems capable of self-assembly. We can expect that in the future synthesis will bring into existence new substances with unique properties that will have impacts as profound as those resulting from syntheses of therapeutics and polymeric materials.

Alkylation of Enolates and Other Carbon Nucleophiles

Introduction

Carbon-carbon bond formation is the basis for the construction of the molecular framework of organic molecules by synthesis. One of the fundamental processes for carbon-carbon bond formation is a reaction between a nucleophilic and an electrophilic carbon. The focus in this chapter is on *enolates*, *imine anions*, and *enamines*, which are carbon nucleophiles, and their reactions with *alkylating agents*. Mechanistically, these are usually S_N2 reactions in which the carbon nucleophile displaces a halide or other leaving group with inversion of configuration at the alkylating group. Efficient carbon-carbon bond formation requires that the S_N2 alkylation be the dominant reaction. The crucial factors that must be considered include: (1) the conditions for generation of the carbon nucleophile; (2) the effect of the reaction conditions on the structure and reactivity of the nucleophile; and (3) the regio- and stereo-selectivity of the alkylation reaction. The reaction can be applied to various carbonyl compounds, including ketones, esters, and amides.

These reactions introduce a new substituent α to the carbonyl group and constitute an important method for this transformation. In the retrosynthetic sense, the disconnection is between the α -carbon and a potential alkylating agent.

There are similar reactions involving nitrogen analogs called *imine anions*. The alkylated imines can be hydrolyzed to the corresponding ketone, and this reaction is discussed in Section 1.3.

Either enolate or imine anions can be used to introduce alkyl α -substituents to a carbonyl group. Because the reaction involves a nucleophilic substitution, primary groups are the best alkylating agents, with methyl, allyl, and benzyl compounds being particularly reactive. Secondary groups are less reactive and are likely to give lower yields because of competing elimination. Tertiary and aryl groups cannot be introduced by an $\text{S}_{\text{N}}2$ mechanism.

1.1. Generation and Properties of Enolates and Other Stabilized Carbanions

1.1.1. Generation of Enolates by Deprotonation

The fundamental aspects of the structure and stability of carbanions were discussed in Chapter 6 of Part A. In the present chapter we relate the properties and reactivity of carbanions stabilized by carbonyl and other EWG substituents to their application as nucleophiles in synthesis. As discussed in Section 6.3 of Part A, there is a fundamental relationship between the stabilizing functional group and the acidity of the C–H groups, as illustrated by the pK data summarized in Table 6.7 in Part A. These pK data provide a basis for assessing the stability and reactivity of carbanions. The acidity of the reactant determines which bases can be used for generation of the anion. Another crucial factor is the distinction between *kinetic or thermodynamic control of enolate formation by deprotonation* (Part A, Section 6.3), which determines the enolate composition. Fundamental mechanisms of $\text{S}_{\text{N}}2$ alkylation reactions of carbanions are discussed in Section 6.5 of Part A. A review of this material may prove helpful.

A primary consideration in the generation of an enolate or other stabilized carbanion by deprotonation is the choice of base. In general, reactions can be carried out under conditions in which the enolate is *in equilibrium* with its conjugate acid or under which the reactant is *completely converted* to its conjugate base. The key determinant is the amount and strength of the base. For complete conversion, the base must be derived from a substantially weaker acid than the reactant. Stated another way, the reagent must be a stronger base than the anion of the reactant. Most current procedures for alkylation of enolates and other carbanions involve complete conversion to the anion. Such procedures are generally more amenable to both regiochemical and stereochemical control than those in which there is only a small equilibrium concentration of the enolate. The solvent and other coordinating or chelating additives also have strong effects on the structure and reactivity of carbanions formed by

deprotonation. The nature of the solvent determines the degree of ion pairing and aggregation, which in turn affect reactivity.

Table 1.1 gives approximate pK data for various functional groups and some of the commonly used bases. The strongest acids appear at the top of the table and the strongest bases at the bottom. The values listed as pK_{ROH} are referenced to water and are appropriate for hydroxylic solvents. Also included in the table are pK values determined in dimethyl sulfoxide (pK_{DMSO}). The range of acidities that can be measured directly in DMSO is greater than that in protic media, thereby allowing direct comparisons between weakly acidic compounds to be made more confidently. The pK values in DMSO are normally larger than in water because water stabilizes anions more effectively, by hydrogen bonding, than does DMSO. Stated another way, many anions are more strongly basic in DMSO than in water. This relationship is particularly apparent for the oxy anion bases, such as acetate, hydroxide, and the alkoxides, which are much more basic in DMSO than in protic solvents. At the present time, the pK_{DMSO} scale includes the widest variety of structural types of synthetic interest.¹ The pK values collected in Table 1.1 provide an ordering of some important

a. From F. G. Bordwell, *Acc. Chem. Res.*, **21**, 456 (1988).

b. In THF; R. R. Fraser and T. S. Mansour, *J. Org. Chem.*, **49**, 3442 (1984).

¹. F. G. Bordwell, *Acc. Chem. Res.*, **21**, 456 (1988).

substituents with respect to their ability to stabilize carbanions. The order indicated is $\text{NO}_2 > \text{COR} > \text{CN} \sim \text{CO}_2\text{R} > \text{SO}_2\text{R} > \text{SOR} > \text{Ph} \sim \text{SR} > \text{H} > \text{R}$. Familiarity with the relative acidity and approximate pK values is important for an understanding of the reactions discussed in this chapter.

There is something of an historical division in synthetic procedures involving carbanions as nucleophiles in alkylation reactions.² As can be seen from Table 1.1, β -diketones, β -ketoesters, malonates, and other compounds with two stabilizing groups have pK values slightly below ethanol and the other common alcohols. As a result, these compounds can be converted completely to enolates by sodium or potassium alkoxides. These compounds were the usual reactants in carbanion alkylation reactions until about 1960. Often, the second EWG is extraneous to the overall purpose of the synthesis and its removal requires an extra step. After 1960, procedures using aprotic solvents, especially THF, and amide bases, such as lithium di-isopropylamide (LDA) were developed. The dialkylamines have a pK around 35. These conditions permit the conversion of monofunctional compounds with $pK > 20$, especially ketones, esters, and amides, completely to their enolates. Other bases that are commonly used are the anions of hexaalkyldisilylamines, especially hexamethyldisilazane.³ The lithium, sodium, and potassium salts are abbreviated LiHMDS, NaHMDS, and KHMDS. The disilylamines have a pK around 30.⁴ The basicity of both dialkylamides and hexaalkyldisilylamides tends to increase with branching in the alkyl groups. The more branched amides also exhibit greater steric discrimination. An example is lithium tetramethylpiperidide, LiTMP, which is sometimes used as a base for deprotonation.⁵ Other strong bases, such as amide anion ($^-\text{NH}_2$), the conjugate base of DMSO (sometimes referred to as the “dimsyl” anion),⁶ and triphenylmethyl anion, are capable of effecting essentially complete conversion of a ketone to its enolate. Sodium hydride and potassium hydride can also be used to prepare enolates from ketones, although the reactivity of the metal hydrides is somewhat dependent on the means of preparation and purification of the hydride.⁷

By comparing the approximate pK values of the bases with those of the carbon acid of interest, it is possible to estimate the position of the acid-base equilibrium for a given reactant-base combination. For a carbon acid C-H and a base B-H ,

$$K_{a(\text{C-H})} = \frac{[\text{C}^-][\text{H}^+]}{[\text{C-H}]} \text{ and } K_{a(\text{B-H})} = \frac{[\text{B}^-][\text{H}^+]}{[\text{B-H}]}$$

at equilibrium

$$\frac{K_{a(\text{C-H})}[\text{C-H}]}{[\text{C}^-]} = \frac{K_{a(\text{B-H})}[\text{B-H}]}{[\text{B}^-]}$$

for the reaction

$$K = \frac{[\text{B-H}][\text{C}^-]}{[\text{C-H}][\text{B}^-]} = \frac{K_{a(\text{C-H})}}{K_{a(\text{B-H})}}$$

If we consider the case of a simple alkyl ketone in a protic solvent, for example, we see that hydroxide ion or primary alkoxide ions will convert only a fraction of a ketone to its anion.

The slightly more basic tertiary alkoxides are comparable to the enolates in basicity, and a more favorable equilibrium will be established with such bases.

Note also that dialkyl ketones such as acetone and 3-pentanone are slightly *more acidic* than the simple alcohols in DMSO. Use of alkoxide bases in DMSO favors enolate formation. For the amide bases, $K_{a(\text{B-H})} \ll K_{a(\text{C-H})}$, and complete formation of the enolate occurs.

It is important to keep the position of the equilibria in mind as we consider reactions of carbanions. The base and solvent used determine the extent of deprotonation. Another important physical characteristic that has to be kept in mind is the degree of aggregation of the carbanion. Both the solvent and the cation influence the state of aggregation. This topic is discussed further in Section 1.1.3.

1.1.2. Regioselectivity and Stereoselectivity in Enolate Formation from Ketones and Esters

Deprotonation of the corresponding carbonyl compound is a fundamental method for the generation of enolates, and we discuss it here for ketones and esters. An unsymmetrical dialkyl ketone can form two *regioisomeric* enolates on deprotonation.

Full exploitation of the synthetic potential of enolates requires control over the regioselectivity of their formation. Although it may not be possible to direct deprotonation so as to form one enolate to the exclusion of the other, experimental conditions can often be chosen to favor one of the regioisomers. The composition of an enolate mixture can be governed by kinetic or thermodynamic factors. The enolate ratio is governed

by *kinetic control* when the product composition is determined by the *relative rates of the competing proton abstraction reactions*.

Kinetic control of isomeric enolate composition

By adjusting the conditions of enolate formation, it is possible to establish either kinetic or thermodynamic control. *Conditions for kinetic control of enolate formation are those in which deprotonation is rapid, quantitative, and irreversible.*⁸ This requirement is met experimentally by using a very strong base such as LDA or LiHMDS in an aprotic solvent in the absence of excess ketone. Lithium is a better counterion than sodium or potassium for regioselective generation of the kinetic enolate, as it maintains a tighter coordination at oxygen and reduces the rate of proton exchange. Use of an aprotic solvent is essential because protic solvents permit enolate equilibration by reversible protonation-deprotonation, which gives rise to the thermodynamically controlled enolate composition. Excess ketone also catalyzes the equilibration by proton exchange.

Scheme 1.1 shows data for the regioselectivity of enolate formation for several ketones under various reaction conditions. A consistent relationship is found in these and related data. *Conditions of kinetic control usually favor formation of the less-substituted enolate*, especially for methyl ketones. The main reason for this result is that removal of a less hindered hydrogen is faster, for steric reasons, than removal of a more hindered hydrogen. Steric factors in ketone deprotonation are accentuated by using bulky bases. The most widely used bases are LDA, LiHMDS, and NaHMDS. Still more hindered disilylamides such as hexaethyldisilylamide⁹ and *bis*-(dimethylphenylsilyl)amide¹⁰ may be useful for specific cases.

The equilibrium ratios of enolates for several ketone-enolate systems are also shown in Scheme 1.1. Equilibrium among the various enolates of a ketone can be established by the presence of an excess of ketone, which permits reversible proton transfer. Equilibration is also favored by the presence of dissociating additives such as HMPA. The composition of the equilibrium enolate mixture is usually more closely balanced than for kinetically controlled conditions. In general, the more highly substituted enolate is the preferred isomer, but if the alkyl groups are sufficiently branched as to interfere with solvation, there can be exceptions. This factor, along with CH₃/CH₃ steric repulsion, presumably accounts for the stability of the less-substituted enolate from 3-methyl-2-butanone (Entry 3).

b. C. H. Heathcock, C. T. Buse, W. A. Kleschick, M. C. Pirrung, J. E. Sohn, and J. Lampe, *J. Org. Chem.*, **45**, 1066 (1980); L. Xie, K. Vanlandeghem, K. M. Isenberger, and C. Bernier, *J. Org. Chem.* **68**, 641 (2003).

The acidifying effect of an adjacent phenyl group outweighs steric effects in the case of 1-phenyl-2-propanone, and as a result the conjugated enolate is favored by both kinetic and thermodynamic conditions (Entry 5).

For cyclic ketones conformational factors also come into play in determining enolate composition. 2-Substituted cyclohexanones are kinetically deprotonated at the C(6) methylene group, whereas the more-substituted C(2) enolate is slightly favored

at equilibrium (Entries 6 and 7). A 3-methyl group has a significant effect on the regiochemistry of kinetic deprotonation but very little effect on the thermodynamic stability of the isomeric enolates (Entry 8).

Many enolates can exist as both *E*- and *Z*-isomers.¹¹ The synthetic importance of LDA and HMDS deprotonation has led to studies of enolate stereochemistry under various conditions. In particular, the stereochemistry of some enolate reactions depends on whether the *E*- or *Z*-isomer is involved. Deprotonation of 2-pentanone was examined with LDA in THF, with and without HMPA. C(1) deprotonation is favored under both conditions, but the *Z*:*E* ratio for C(3) deprotonation is sensitive to the presence of HMPA.¹² More *Z*-enolate is formed when HMPA is present.

Ratio C(1):C(3) deprotonation	Ratio <i>Z</i> : <i>E</i> for C(3) deprotonation
0° C, THF alone	7.9
-60° C, THF alone	7.1
0° C, THF-HMPA	8.0
-60° C, THF-HMPA	5.6

These and other related enolate ratios are interpreted in terms of a tight, reactant-like cyclic TS in THF and a looser TS in the presence of HMPA. The cyclic TS favors the *E*-enolate, whereas the open TS favors the *Z*-enolate. The effect of the HMPA is to solvate the Li⁺ ion, reducing the importance of Li⁺ coordination with the carbonyl oxygen.¹³

¹¹. The enolate oxygen is always taken as a high-priority substituent in assigning the *E*- or *Z*-configuration.

In contrast to LDA, LiHMDS favors the *Z*-enolate.¹⁴ Certain other bases show a preference for formation of the *Z*-enolate. For example, lithium 2,4,6-trichloroanilide, lithium diphenylamide, and lithium trimethylsilylanilide show nearly complete *Z*-selectivity with 2-methyl-3-pentanone.¹⁵

The *Z*-selectivity seems to be associated primarily with reduced basicity of the amide anion. It is postulated that the shift to *Z*-stereoselectivity is the result of a looser TS, in which the steric effects of the chair TS are reduced.

Strong effects owing to the presence of lithium halides have been noted. With 3-pentanone, the *E*:*Z* ratio can be improved from 10:1 to 60:1 by addition of one equivalent of LiBr in deprotonation by LiTMP.¹⁶ (Note a similar effect for 2-methyl-3-pentanone in Table 1.2) NMR studies show that the addition of the halides leads to formation of mixed 1:1 aggregates, but precisely how this leads to the change in stereoselectivity has not been unraveled. A crystal structure has been determined for a 2:1:4:1 complex of the enolate of methyl *t*-butyl ketone, with an HMDS anion, four lithium cations, and one bromide.¹⁷ This structure, reproduced in Figure 1.1, shows that the lithium ions are clustered around the single bromide, with the enolate oxygens bridging between two lithium ions. The amide base also bridges between lithium ions.

Very significant acceleration in the rate of deprotonation of 2-methylcyclohexanone was observed when triethylamine was included in enolate-forming reactions in toluene. The rate enhancement is attributed to a TS containing LiHMDS dimer and triethylamine. Steric effects in the amine are crucial in selective stabilization of the TS and the extent of acceleration that is observed.¹⁸

These effects of LiBr and triethylamine indicate that there is still much to be learned about deprotonation and that there is potential for further improvement in regio- and stereoselectivity.

Some data on the stereoselectivity of enolate formation from both esters and ketones is given in Table 1.2. The switch from *E* to *Z* in the presence of HMPA is particularly prominent for ester enolates. There are several important factors in determining regio- and stereoselectivity in enolate formation, including the strength of the base, the identity of the cation, and the nature of the solvent and additives. In favorable cases such as 2-methyl-3-pentanone and ethyl propanoate, good selectivity is possible for both stereoisomers. In other cases, such as 2,2-dimethyl-3-pentanone, the inherent stability difference between the enolates favors a single enolate, regardless of conditions.

Chelation affects the stereochemistry of enolate formation. For example, the formation of the enolates from α -siloxyesters is *Z* for LiHMDS, but *E* for LiTMP.¹⁹

It has been suggested that this stereoselectivity might arise from a chelated TS in the case of the less basic LiHMDS.

Kinetically controlled deprotonation of α,β -unsaturated ketones usually occurs preferentially at the α' -carbon adjacent to the carbonyl group. The polar effect of the carbonyl group is probably responsible for the faster deprotonation at this position.

Ref. 20

20. R. A. Lee, C. McAndrews, K. M. Patel, and W. Reusch, *Tetrahedron Lett.*, 965 (1973).

Under conditions of thermodynamic control, however, it is the enolate corresponding to deprotonation of the γ -carbon that is present in the greater amount.

Ref. 21

These isomeric enolates differ in that **1** is fully conjugated, whereas the π system in **2** is cross-conjugated. In isomer **2**, the delocalization of the negative charge is restricted to the oxygen and the α' -carbon, whereas in the conjugated system of **1** the negative charge is delocalized on oxygen and both the α - and γ -carbon.

It is also possible to achieve *enantioselective enolate formation* by using chiral bases. Enantioselective deprotonation requires discrimination between two enantiotopic hydrogens, such as in *cis*-2,6-dimethylcyclohexanone or 4-(*t*-butyl)cyclohexanone. Among the bases that have been studied are chiral lithium amides such as **A** to **D**.²²

Enantioselective enolate formation can also be achieved by *kinetic resolution* through preferential reaction of one of the enantiomers of a racemic chiral ketone such as 2-(*t*-butyl)cyclohexanone (see Section 2.1.8 of Part A to review the principles of kinetic resolution).

Such enantioselective deprotonations depend upon kinetic selection between prochiral or enantiomeric hydrogens and the chiral base, resulting from differences in diastereomeric TSs.²⁷ For example, transition structure **E** has been proposed for deprotonation of 4-substituted cyclohexanones by base **D**.²⁸ This structure includes a chloride generated from trimethylsilyl chloride.

1.1.3. Other Means of Generating Enolates

Reactions other than deprotonation can be used to generate specific enolates under conditions in which lithium enolates do not equilibrate with regio- and stereoisomers. Several methods are shown in Scheme 1.2. Cleavage of trimethylsilyl enol ethers or enol acetates by methyllithium (Entries 1 and 3), depends on the availability of these materials in high purity. Alkoxides can also be used to cleave silyl enol ethers and enol acetates.²⁹ When KO-*t*-Bu is used for the cleavage, subsequent alkylation occurs at the more-substituted position, regardless of which regioisomeric silyl enol ether is used.³⁰ Evidently under these conditions, the potassium enolates equilibrate and the more highly substituted enolate is more reactive.

Trimethylsilyl enol ethers can also be cleaved by tetraalkylammonium fluoride (Entry 2). The driving force for this reaction is the formation of the very strong Si–F bond, which has a bond energy of 142 kcal/mol.³¹ These conditions, too, lead to enolate equilibration.

The composition of the enol ethers trimethylsilyl prepared from an enolate mixture reflects the enolate composition. If the enolate formation can be done with high regioselection, the corresponding trimethylsilyl enol ether can be obtained in high purity. If not, the silyl enol ether mixture must be separated. Trimethylsilyl enol ethers can be prepared directly from ketones. One procedure involves reaction with trimethylsilyl

chloride and a tertiary amine.³² This procedure gives the regioisomers in a ratio favoring the thermodynamically more stable enol ether. Use of *t*-butyldimethylsilyl chloride with potassium hydride as the base also seems to favor the thermodynamic product.³³ Trimethylsilyl trifluoromethanesulfonate (TMS-OTf), which is more reactive, gives primarily the less-substituted trimethylsilyl enol ether.³⁴ Higher ratios of the less-substituted enol ether are obtained by treating a mixture of ketone and trimethylsilyl chloride with LDA at -78°C .³⁵ Under these conditions the kinetically preferred enolate is immediately trapped by reaction with trimethylsilyl chloride. Even greater preferences for the less-substituted silyl enol ether can be obtained by using the more hindered lithium amide from *t*-octyl-*t*-butylamine (LOBA).

Lithium-ammonia reduction of α,β -unsaturated ketones (Entry 6) provides a very useful method for generating specific enolates.³⁶ The starting enones are often readily available and the position of the double bond in the enone determines the structure of the resulting enolate. For acyclic enones, the TMS-Cl trapping of enolates generated by conjugate reduction gives a silyl enol ether having a composition that reflects the conformation of the enone.³⁷ (See Section 2.2.1 of Part A to review enone conformation.)

Trimethylsilyl enol ethers can also be prepared by 1,4-reduction of enones using silanes as reductants. Several effective catalysts have been found,³⁸ of which the most versatile appears to be a Pt complex of divinyltetramethyldisiloxane.³⁹ This catalyst gives good yields of substituted silyl enol ethers (e.g., Scheme 1.2, Entry 7).

Excellent yields of silyl enol have also been obtained from enones using $\text{B}(\text{C}_6\text{F}_5)_3$ as a catalyst.⁴⁰ *t*-Butyldimethylsilyl, triethylsilyl, and other silyl enol ethers can also be made under these conditions.

These and other reductive methods for generating enolates from enones are discussed more fully in Chapter 5.

Another very important method for specific enolate generation is the conjugate addition of organometallic reagents to enones. This reaction, which not only generates a specific enolate, but also adds a carbon substituent, is discussed in Section 8.1.2.3.

1.1.4. Solvent Effects on Enolate Structure and Reactivity

The rate of alkylation of enolate ions is strongly dependent on the solvent in which the reaction is carried out.⁴¹ The relative rates of reaction of the sodium enolate of diethyl *n*-butylmalonate with *n*-butyl bromide are shown in Table 1.3. Dimethyl sulfoxide (DMSO) and *N,N*-dimethylformamide (DMF) are particularly effective in enhancing the reactivity of enolate ions. Both of these are *polar aprotic solvents*. Other

Table 1.3. Relative Alkylation Rates of Sodium Diethyl *n*-Butylmalonate in Various Solvents^a

Solvent	Dielectric constant ϵ	Relative rate
Benzene	2.3	1
Tetrahydrofuran	7.3	14
Dimethoxyethane	6.8	80
<i>N,N</i> -Dimethylformamide	37	970
Dimethyl sulfoxide	47	1420

Tetrahydrofuran (THF) and dimethoxyethane (DME) are slightly polar solvents that are moderately good cation solvators. Coordination to the metal cation involves the oxygen unshared electron pairs. These solvents, because of their lower dielectric constants, are less effective at separating ion pairs and higher aggregates than are the polar aprotic solvents. The structures of the lithium and potassium enolates of methyl *t*-butyl ketone have been determined by X-ray crystallography. The structures are shown in Figures 1.2 and 1.3.⁴³ Whereas these represent the solid state structures,

Fig. 1.3. Potassium enolate of methyl *t*-butyl ketone; open circles are oxygen and small circles are potassium. (a) left panel shows only the enolate structures; (b) right panel shows only the solvating THF molecules. The actual structure is the superposition of both panels. Reproduced from *J. Am. Chem. Soc.*, **108**, 462 (1986), by permission of the American Chemical Society.

⁴³ P. G. Williard and G. B. Carpenter, *J. Am. Chem. Soc.*, **108**, 462 (1986).

the hexameric clusters are a good indication of the nature of the enolates in relatively weakly coordinating solvents. In both structures, series of alternating metal cations and enolate oxygens are assembled in two offset hexagons. The cluster is considerably tighter with Li^+ than with K^+ . The M–O bonds are about 1.9 Å for Li^+ and 2.6 Å for K^+ . The enolate C–O bond is longer (1.34 Å) for Li^+ than for K^+ (1.31 Å), whereas the C=C bond is shorter for Li^+ (1.33 Å) than for K^+ (1.35 Å). Thus, the Li^+ enolate has somewhat more of oxy-anion character and is expected to be a “harder” than the potassium enolate.

Despite the somewhat reduced reactivity of aggregated enolates, THF and DME are the most commonly used solvents for synthetic reactions involving enolate alkylation. They are the most suitable solvents for *kinetic enolate generation* and also have advantages in terms of product workup and purification over the polar aprotic solvents. Enolate reactivity in these solvents can often be enhanced by adding a reagent that can bind alkali metal cations more strongly. Popular choices are HMPA, DMPU, tetramethylethylenediamine (TMEDA), and the crown ethers. TMEDA chelates metal ions through the electron pairs on nitrogen. The crown ethers encapsulate the metal ions through coordination with the ether oxygens. The 18-crown-6 structure is of such a size as to allow sodium or potassium ions to fit in the cavity. The smaller 12-crown-4 binds Li^+ preferentially. The cation complexing agents lower the degree of aggregation of the enolate and metal cations, which results in enhanced reactivity.

The effect of HMPA on the reactivity of cyclopentanone enolate has been examined.⁴⁴ This enolate is primarily a dimer, even in the presence of excess HMPA, but the reactivity increases by a factor of 7500 for a tenfold excess of HMPA at -50°C . The kinetics of the reaction with CH_3I are consistent with the dimer being the active nucleophile. It should be kept in mind that the reactivity of regio- and stereoisomeric enolates may be different and the alkylation product ratio may not reflect the enolate composition. This issue was studied with 2-heptanone.⁴⁵ Although kinetic deprotonation in THF favors the 1-enolate, a nearly equal mixture of C(1) and C(3) alkylation was observed. The inclusion of HMPA improved the C(1) selectivity to 11:1 and also markedly accelerated the rate of the reaction. These results are presumably due to increased reactivity and less competition from enolate isomerization in the presence of HMPA.

The effect of chelating polyamines on the rate and yield of benzylation of the lithium enolate of 1-tetralone was compared with HMPA and DMPU. The triamine

⁴⁵ C. L. Liotta and T. C. Caruso, *Tetrahedron Lett.*, **26**, 1599 (1985).

and tetramine were even more effective than HMPA in promoting reaction.⁴⁶ These results, too, are presumably due to disaggregation of the enolate by the polyamines.

The reactivity of enolates is also affected by the metal counterion. For the most commonly used ions the order of reactivity is $\text{Mg}^{2+} < \text{Li}^+ < \text{Na}^+ < \text{K}^+$. The factors that are responsible for this order are closely related to those described for solvents. The smaller, harder Mg^{2+} and Li^+ cations are more tightly associated with the enolate than are the Na^+ and K^+ ions. The tighter coordination decreases the reactivity of the enolate and gives rise to more highly associated species.

1.2. Alkylation of Enolates⁴⁷

1.2.1. Alkylation of Highly Stabilized Enolates

Relatively acidic compounds such as malonate esters and β -ketoesters were the first class of compounds for which reliable conditions for carbanion alkylation were developed. The alkylation of these relatively acidic compounds can be carried out in alcohols as solvents using metal alkoxides as bases. The presence of two electron-withdrawing substituents facilitates formation of the resulting enolate. Alkylation occurs by an $\text{S}_{\text{N}}2$ process, so the alkylating agent must be reactive toward nucleophilic displacement. Primary halides and sulfonates, especially allylic and benzylic ones, are the most reactive alkylating agents. Secondary systems react more slowly and often give only moderate yields because of competing elimination. Tertiary halides give only elimination products. Methylene groups can be dialkylated if sufficient base and alkylating agent are used. Dialkylation can be an undesirable side reaction if the monoalkyl derivative is the desired product. Sequential dialkylation using two different alkyl groups is possible. Use of dihaloalkanes as alkylating reagents leads to ring formation. The relative rates of cyclization for ω -haloalkyl malonate esters

are 650,000:1:6500:5 for formation of three-, four-, five-, and six-membered rings, respectively.⁴⁸ (See Section 4.3 of Part A to review the effect of ring size on S_N2 reactions.)

Some examples of alkylation reactions involving relatively acidic carbon acids are shown in Scheme 1.3. Entries 1 to 4 are typical examples using sodium ethoxide as the base. Entry 5 is similar, but employs sodium hydride as the base. The synthesis of diethyl cyclobutanedicarboxylate in Entry 6 illustrates ring formation by *intramolecular alkylation reactions*. Additional examples of intramolecular alkylation are considered in Section 1.2.5. Note also the stereoselectivity in Entry 7, where the existing branched substituent leads to a *trans* orientation of the methyl group.

The 2-substituted β -ketoesters (Entries 1, 4, 5, and 7) and malonic ester (Entries 2 and 6) prepared by the methods illustrated in Scheme 1.3 are useful for the synthesis

of ketones and carboxylic acids. Both β -keto acids and malonic acids undergo facile decarboxylation.

β -keto acid: X = alkyl or aryl = ketone
substituted malonic acid: X = OH = substituted acetic acid

Examples of this approach to the synthesis of ketones and carboxylic acids are presented in Scheme 1.4. In these procedures, an ester group is removed by hydrolysis and decarboxylation after the alkylation step. The malonate and acetoacetate carbanions are the *synthetic equivalents* of the simpler carbanions that lack the additional ester substituent. In the preparation of 2-heptanone (Entry 1), for example, ethyl acetoacetate functions

as the synthetic equivalent of acetone. Entries 2 and 3 show synthesis of carboxylic acids via the malonate ester route. Entry 4 is an example of a nitrile synthesis, starting with ethyl cyanoacetate as the carbon nucleophile. The cyano group also facilitates decarboxylation. Entry 5 illustrates an alternative decarboxylation procedure in which lithium iodide is used to cleave the β -ketoester by nucleophilic demethylation.

It is also possible to use the dilithium derivative of acetoacetic acid as the synthetic equivalent of acetone enolate.⁴⁹ In this case, the hydrolysis step is unnecessary and decarboxylation can be done directly on the alkylation product.

Similarly, the dilithium dianion of monoethyl malonate is easily alkylated and the product decarboxylates after acidification.⁵⁰

1.2.2. Alkylation of Ketone Enolates

The preparation of ketones and ester from β -dicarbonyl enolates has largely been supplanted by procedures based on selective enolate formation. These procedures permit direct alkylation of ketone and ester enolates and avoid the hydrolysis and decarboxylation of keto ester intermediates. The development of conditions for stoichiometric formation of both kinetically and thermodynamically controlled enolates has permitted the extensive use of enolate alkylation reactions in multistep synthesis of complex molecules. One aspect of the alkylation reaction that is crucial in many cases is the stereoselectivity. The alkylation has a stereoelectronic preference for approach of the electrophile perpendicular to the plane of the enolate, because the π electrons are involved in bond formation. A major factor in determining the stereoselectivity of ketone enolate alkylations is the difference in steric hindrance on the two faces of the enolate. The electrophile approaches from the less hindered of the two faces and the degree of stereoselectivity depends on the steric differentiation. Numerous examples of such effects have been observed.⁵¹ In ketone and ester enolates that are exocyclic to a conformationally biased cyclohexane ring there is a small preference for

⁴⁹ R. A. Kjonaas and D. D. Patel, *Tetrahedron Lett.*, **25**, 5467 (1984).

⁵⁰ J. E. McMurry and J. H. Musser, *J. Org. Chem.*, **40**, 2556 (1975).

⁵¹ For reviews, see D. A. Evans, in *Asymmetric Synthesis*, Vol. 3, J. D. Morrison, ed., Academic Press, New York, 1984, Chap. 1; D. Caine, in *Carbon-Carbon Bond Formation*, R. L. Augustine, ed., Marcel Dekker, New York, 1979, Chap. 2.

the electrophile to approach from the equatorial direction.⁵² If the axial face is further hindered by addition of a substituent, the selectivity is increased.

For simple, conformationally biased cyclohexanone enolates such as that from 4-*t*-butylcyclohexanone, there is little steric differentiation. The alkylation product is a nearly 1:1 mixture of the *cis* and *trans* isomers.

Ref. 53

The *cis* product must be formed through a TS with a twistlike conformation to adhere to the requirements of stereoelectronic control. The fact that this pathway is not disfavored is consistent with other evidence that the TS in enolate alkylations occurs *early* and reflects primarily the structural features of the reactant, not the product. A late TS would disfavor the formation of the *cis* isomer because of the strain associated with the nonchair conformation of the product.

The introduction of an alkyl substituent at the α -carbon in the enolate enhances stereoselectivity somewhat. This is attributed to a steric effect in the enolate. To minimize steric interaction with the solvated oxygen, the alkyl group is distorted somewhat from coplanarity, which biases the enolate toward attack from the axial direction. The alternate approach from the upper face increases the steric interaction by forcing the alkyl group to become eclipsed with the enolate oxygen.⁵⁴

⁵² A. P. Krapcho and E. A. Dundulis, *J. Org. Chem.*, **45**, 3236 (1980); H. O. House and T. M. Bare, *J. Org. Chem.*, **33**, 943 (1968).

⁵³ H. O. House, B. A. Terfertiller, and H. D. Olmstead, *J. Org. Chem.*, **33**, 935 (1968).

⁵⁴ H. O. House and M. J. Umen, *J. Org. Chem.*, **38**, 1000 (1973).

When an additional methyl substituent is placed at C(3), there is a strong preference for alkylation *anti* to the 3-methyl group. This is attributed to the conformation of the enolate, which places the C(3) methyl in a pseudoaxial orientation because of allylic strain (see Part A, Section 2.2.1). The axial C(3) methyl then shields the lower face of the enolate.⁵⁵

The enolates of 1- and 2-decalone derivatives provide further insight into the factors governing stereoselectivity in enolate alkylations. The 1(9)-enolate of 1-decalone shows a preference for alkylation to give the *cis* ring juncture, and this is believed to be due primarily a steric effect. The upper face of the enolate presents three hydrogens in a 1,3-diaxial relationship to the approaching electrophile. The corresponding hydrogens on the lower face are equatorial.⁵⁶

The 2(1)-enolate of *trans*-2-decalone is preferentially alkylated by an axial approach of the electrophile.

The stereoselectivity is enhanced if there is an alkyl substituent at C(1). The factors operating in this case are similar to those described for 4-*t*-butylcyclohexanone. The *trans*-decalone framework is conformationally rigid. Axial attack from the lower face leads directly to the chair conformation of the product. The 1-alkyl group enhances this stereoselectivity because a steric interaction with the solvated enolate oxygen distorts the enolate to favor the axial attack.⁵⁷ The placement of an axial methyl group at C(10) in a 2(1)-decalone enolate introduces a 1,3-diaxial interaction with the approaching electrophile. The preferred alkylation product results from approach on the opposite side of the enolate.

⁵⁵. R. K. Boeckman, Jr., *J. Org. Chem.*, **38**, 4450 (1973).

⁵⁶. H. O. House and B. M. Trost, *J. Org. Chem.*, **30**, 2502 (1965).

⁵⁷. R. S. Mathews, S. S. Grigenti, and E. A. Folkers, *J. Chem. Soc., Chem. Commun.*, 708 (1970); P. Lansbury and G. E. DuBois, *Tetrahedron Lett.*, 3305 (1972).

The prediction and interpretation of alkylation stereochemistry requires consideration of conformational effects in the enolate. The decalone enolate **3** was found to have a strong preference for alkylation to give the *cis* ring junction, with alkylation occurring *cis* to the *t*-butyl substituent.⁵⁸

According to molecular mechanics (MM) calculations, the minimum energy conformation of the enolate is a twist-boat (because the chair leads to an axial orientation of the *t*-butyl group). The enolate is convex in shape with the second ring shielding the bottom face of the enolate, so alkylation occurs from the top.

Houk and co-workers examined the role of torsional effects in the stereoselectivity of enolate alkylation in five-membered rings, and their interpretation can explain the preference for C(5) alkylation *syn* to the 2-methyl group in *trans*-2,3-dimethylcyclopentanone.⁵⁹

The *syn* TS is favored by about 1 kcal/mol, owing to reduced eclipsing, as illustrated in Figure 1.4. An experimental study using the kinetic enolate of 3-(*t*-butyl)-2-methylcyclopentanone in an alkylation reaction with benzyl iodide gave an 85:15 preference for the predicted *cis*-2,5-dimethyl derivative.

In acyclic systems, the enolate conformation comes into play. β,β -Disubstituted enolates prefer a conformation with the hydrogen eclipsed with the enolate double bond. In unfunctionalized enolates, alkylation usually takes place *anti* to the larger substituent, but with very modest stereoselectivity.

Ref. 60

These examples illustrate the issues that must be considered in analyzing the stereoselectivity of enolate alkylation. *The major factors are the conformation of the enolate, the stereoelectronic requirement for an approximately perpendicular trajectory, the steric preference for the least hindered path of approach, and minimization of torsional strain.* In cyclic systems the ring geometry and positioning of substituents are often the dominant factors. For acyclic enolates, the conformation and the degree of steric discrimination govern the stereoselectivity.

For enolates with additional functional groups, chelation may influence stereoselectivity. Chelation-controlled alkylation has been examined in the context of the synthesis of a polyol lactone (–)-discodermolide. The lithium enolate **4** reacts with the allylic iodide **5** in a hexane:THF solvent mixture to give a 6:1 ratio favoring the desired stereoisomer. Use of the sodium enolate gives the opposite stereoselectivity, presumably because of the loss of chelation.⁶¹ The solvent seems to be quite important in promoting chelation control.

to the more-substituted enolate precedes alkylation. Entries 3 and 4 show regiospecific generation of enolates by reaction of silyl enol ethers with methyllithium. Alkylation can also be carried out using silyl enol ethers by generating the enolate by fluoride ion.⁶³ Anhydrous tetraalkylammonium fluoride salts in anhydrous are normally the fluoride ion source.⁶⁴ Entries 5 and 6 illustrate this method. Entry 7 shows the kinetic deprotonation of 3-methylbutanone, followed by alkylation with a functionalized allylic iodide. Entries 8, 9, and 10 are examples of alkylation of enolates generated by reduction of enones. Entry 10 illustrates the preference for axial alkylation of the 2-(1)-decalone enolate.

In enolates formed by proton abstraction from α,β -unsaturated ketones, there are three potential sites for attack by electrophiles: the oxygen, the α -carbon, and the γ -carbon. The kinetically preferred site for both protonation and alkylation is the α -carbon.⁶⁵

The selectivity for electrophilic attack at the α -carbon presumably reflects a greater negative charge, as compared with the γ -carbon.

Protonation of the enolate provides a method for converting α,β -unsaturated ketones and esters to the less stable β,γ -unsaturated isomers.

Ref. 66

1.2.3. Alkylation of Aldehydes, Esters, Carboxylic Acids, Amides, and Nitriles

Among the compounds capable of forming enolates, the alkylation of ketones has been most widely studied and applied synthetically. Similar reactions of esters, amides, and nitriles have also been developed. Alkylation of aldehyde enolates is not very common. One reason is that aldehydes are rapidly converted to aldol addition products by base. (See Chapter 2 for a discussion of this reaction.) Only when the enolate can be rapidly and quantitatively formed is aldol formation avoided. Success has been reported using potassium amide in liquid ammonia⁶⁷ and potassium hydride in tetrahydrofuran.⁶⁸ Alkylation via enamines or enamine anions provides a more general method for alkylation of aldehydes. These reactions are discussed in Section 1.3.

Ref. 68

Ester enolates are somewhat less stable than ketone enolates because of the potential for elimination of alkoxide. The sodium and potassium enolates are rather unstable, but Rathke and co-workers found that the lithium enolates can be generated at -78°C .⁶⁹ Alkylations of simple esters require a strong base because relatively weak bases such as alkoxides promote condensation reactions (see Section 2.3.1). The successful formation of ester enolates typically involves an amide base, usually LDA or LiHDMS, at low temperature.⁷⁰ The resulting enolates can be successfully alkylated with alkyl bromides or iodides. HMPA is sometimes added to accelerate the alkylation reaction.

In acyclic systems, the stereochemistry of alkylation depends on steric factors. Stereoselectivity is low for small substituents.⁷¹

When a larger substituent is present, the reaction becomes much more selective. For example, a β -dimethylphenylsilyl substituent leads to more than 95:5 *anti* alkylation in ester enolates.⁷²

This stereoselectivity is the result of the conformation of the enolate and steric shielding by the silyl substituent.

This directive effect has been employed in stereoselective synthesis.

Ref. 73

A careful study of the alkylation of several enolates of dialkyl malate esters has been reported.⁷⁴ These esters form dianions resulting from deprotonation of the hydroxy

Nitriles can also be converted to anions and alkylated. Acetonitrile ($\text{p}K_{\text{DMSO}} = 31.3$) can be deprotonated, provided a strong nonnucleophilic base such as LDA is used.

Ref. 77

Phenylacetonitrile ($\text{p}K_{\text{DMSO}} = 21.9$) is considerably more acidic than acetonitrile. Dialkylation has been used in the synthesis of meperidine, an analgesic substance.⁷⁸

We will see in Section 1.2.6 that the enolates of *imides* are very useful in synthesis. Particularly important are the enolates of chiral *N*-acyloxazolidinones.

Scheme 1.6 gives some examples of alkylation of esters, amides, and nitriles. Entries 1 and 2 are representative ester alkylations involving low-temperature

deprotonation by hindered lithium amides. Entries 3 to 7 are lactone alkylations. Entry 3 involves two successive alkylation steps, with the second group being added from the more open face of the enolate. Entry 4 also illustrates stereoselectivity based on a steric effect. Entry 5 shows alkylation at both the enolate and a hydroxy group. Entry 6 is a step in the synthesis of the C(33)–C(37) fragment of the antibiotic amphotericin B. Note that in this case although the hydroxy group is deprotonated it is not methylated under the reaction conditions being used. Entry 7 is a challenging alkylation of a sensitive β-lactone. Although the corresponding saturated halide was not reactive enough, the allylic iodide gave a workable yield. Entry 8 is an alkylation of a lactam. Entries 9 and 10 are nitrile alkylations, the latter being intramolecular.

1.2.4. Generation and Alkylation of Dianions

In the presence of a very strong base, such as an alkyllithium, sodium or potassium hydride, sodium or potassium amide, or LDA, 1,3-dicarbonyl compounds can be converted to their *dianions* by two sequential deprotonations.⁷⁹ For example, reaction of benzoylacetone with sodium amide leads first to the enolate generated by deprotonation at the more acidic methylene group between the two carbonyl groups. A second equivalent of base deprotonates the benzyl methylene group to give a dianediolate.

Ref. 80

Alkylation of dianions occurs at the *more basic carbon*. This technique permits alkylation of 1,3-dicarbonyl compounds to be carried out cleanly at the less acidic position. Since, as discussed earlier, alkylation of the monoanion occurs at the carbon between the two carbonyl groups, the site of monoalkylation can be controlled by choice of the amount and nature of the base. A few examples of the formation and alkylation of dianions are collected in Scheme 1.7. In each case, alkylation occurs at the less stabilized anionic carbon. In Entry 3, the α -formyl substituent, which is removed after the alkylation, serves to direct the alkylation to the methyl-substituted carbon. Entry 6 is a step in the synthesis of artemisinin, an antimalarial component of a Chinese herbal medicine. The sulfoxide serves as an anion-stabilizing group and the dianion is alkylated at the less acidic α -position. Note that this reaction is also stereoselective for the *trans* isomer. The phenylsulfinyl group is removed reductively by aluminum. (See Section 5.6.2 for a discussion of this reaction.)

1.2.5. Intramolecular Alkylation of Enolates

There are many examples of formation of three- through seven-membered rings by intramolecular enolate alkylation. The reactions depend on attainment of a TS having an approximately linear arrangement of the nucleophilic carbon, the electrophilic carbon, and the leaving group. Since the HOMO of the enolate (ψ_2) is involved, the approach must be approximately perpendicular to the enolate.⁸¹ In intramolecular alkylation, these stereoelectronic restrictions on the direction of approach of the electrophile to the enolate become important. Baldwin has summarized the general principles that govern the energetics of intramolecular ring-closure reactions.⁸² Analysis of the stereochemistry of intramolecular enolate alkylation requires consideration of both the direction of approach and enolate conformation. The intramolecular alkylation reaction of **7** gives exclusively **8**, having the *cis* ring juncture.⁸³ The alkylation probably occurs through a TS like **F**. The TS geometry permits the π electrons of the enolate to achieve an approximately colinear alignment with the sulfonate leaving group. The TS **G** for

formation of the *trans* ring junction would be more strained because of the necessity to span the distance to the opposite face of the enolate π system.

Geometric factors in the TS are also responsible for differences in the case of cyclization of enolates **9** and **10**.⁸⁴

A number of examples of good stereoselectivity based on substituent control of reactant conformation have been identified. For example, **11** gives more than 96% stereoselectivity for the isomer in which the methyl and 2-propenyl groups are *cis*.⁸⁵

Similar *cis* stereoselectivity was observed in formation of four- and five-membered rings.⁸⁶ The origin of this stereoselectivity was probed systematically by a study in which a methyl substituent was placed at the C(3), C(4), C(5), and C(6) positions of ethyl 7-bromoheptanoate. Good (> 93%) stereoselectivity was noted for all but the C(5) derivative.⁸⁷ These results are consistent with a chairlike TS with the enolate in an equatorial-like position. In each case the additional methyl group can occupy an equatorial position. The reduced selectivity of the 5-methyl isomer may be due to the fact that the methyl group is farther from the reaction site than in the other cases.

An intramolecular alkylation following this stereochemical pattern was used in the synthesis of (-)-fumagillol, with the alkadienyl substituent exerting the dominant conformational effect.⁸⁸

Scheme 1.8 shows some intramolecular enolate alkylations. The reactions in Section A involve alkylation of ketone enolates. Entry 1 is a case of α -alkylation of a conjugated dienolate. In this case, the α -alkylation is also favored by ring strain effects because γ -alkylation would lead to a four-membered ring. The intramolecular alkylation in Entry 2 was used in the synthesis of the terpene seychellene.

Entries 3 to 6 are examples of ester enolate alkylations. These reactions show stereoselectivity consistent with cyclic TSs in which the hydrogen is eclipsed with the enolate and the larger substituent is pseudoequatorial. Entries 4 and 5 involve S_N2' substitutions of allylic halides. The formation of the six- and five-membered rings, respectively, is the result of ring size preferences with $5 > 7$ and $6 > 8$. In Entry 4, reaction occurs through a chairlike TS with the tertiary C(5) substituent controlling the conformation. The cyclic TS results in a *trans* relationship between the ester and vinylic substituents.

Entry 6 results in the formation of a four-membered ring and shows good stereoselectivity. Entry 7 is a step in the synthesis of a tetracyclic lactone, quadrone, that is isolated from a microorganism. Entry 8 is a step in a multikilo synthesis of an endothelin receptor antagonist called cyclopentapyridine I. The phosphate group was chosen as a leaving group because sulfonates were too reactive at the diaryl carbinol site. The reaction was shown to go with inversion of configuration.

1.2.6. Control of Enantioselectivity in Alkylation Reactions

The alkylation of an enolate creates a new stereogenic center when the α -substituents are nonidentical. In enantioselective synthesis, it is necessary to control the direction of approach and thus the configuration of the new stereocenter.

Enantioselective enolate alkylation can be done using chiral auxiliaries. (See Section 2.6 of Part A to review the role of chiral auxiliaries in control of reaction stereochemistry.) The most frequently used are the *N*-acyloxazolidinones.⁸⁹ The 4-isopropyl and 4-benzyl derivatives, which can be obtained from valine and phenylalanine, respectively, and the *cis*-4-methyl-5-phenyl derivatives are readily available. Another useful auxiliary is the 4-phenyl derivative.⁹⁰

Several other oxazolidinones have been developed for use as chiral auxiliaries. The 4-isopropyl-5,5-dimethyl derivative gives excellent enantioselectivity.⁹¹ 5,5-Diaryl derivatives are also quite promising.⁹²

The reactants are usually *N*-acyl derivatives. The lithium enolates form chelate structures with *Z*-stereochemistry at the double bond. The ring substituents then govern the preferred direction of approach.

⁹¹ S. D. Bull, S. G. Davies, S. Jones, and H. J. Sangane, *J. Chem. Soc., Perkin Trans. 1*, 387 (1999); S. G. Davies and H. J. Sangane, *Tetrahedron: Asymmetry*, **6**, 671 (1995); S. D. Bull, S. G. Davies, R. L. Nicholson, H. J. Sangane, and A. D. Smith, *Org. Biomed. Chem.*, **1**, 2886 (2003).

⁹² T. Hintermann and D. Seebach, *Helv. Chim. Acta*, **81**, 2093 (1998); C. L. Gibson, K. Gillon, and S. Cook, *Tetrahedron Lett.*, **39**, 6733 (1998).

In **12** the upper face is shielded by the isopropyl group, whereas in **13** the lower face is shielded by the methyl and phenyl groups. As a result, alkylation of the two derivatives gives products of the opposite configuration. The initial alkylation product ratios are typically 95:5 in favor of the major isomer. Since these products are diastereomeric mixtures, they can be separated and purified. Subsequent hydrolysis or alcoholysis provides acids or esters in enantiomerically enriched form. Alternatively, the acyl imides can be reduced to alcohols or aldehydes. The final products can often be obtained in greater than 99% enantiomeric purity.

A number of other types of chiral auxiliaries have been employed in enolate alkylation. Excellent results are obtained using amides of pseudoephedrine. Alkylation occurs *anti* to the α -oxybenzyl group.⁹³ The reactions involve the *Z*-enolate and there is likely bridging between the two lithium cations, perhaps by di-(isopropyl)amine.⁹⁴

Both enantiomers of the auxiliary are available, so either enantiomeric product can be obtained. This methodology has been applied to a number of enantioselective syntheses.⁹⁵ For example, the glycine derivative **14** can be used to prepare α -amino acid analogs.⁹⁶

Enolates of phenylglycinol amides also exhibit good diastereoselectivity.⁹⁷ A chelating interaction with the deprotonated hydroxy group is probably involved here as well.

The *trans*-2-naphthyl cyclohexyl sulfone **15** can be prepared readily in either enantiomeric form. The corresponding ester enolates can be alkylated in good yield and diastereoselectivity.⁹⁸ In this case, the steric shielding is provided by the naphthyl

group and there is probably also a $\pi - \pi$ interaction between the naphthalene ring and the enolate.

As with the acyl oxazolidinone auxiliaries, each of these systems permits hydrolytic removal and recovery of the chiral auxiliary.

Scheme 1.9 gives some examples of diastereoselective enolate alkylations. Entries 1 to 6 show the use of various *N*-acyloxazolidinones and demonstrate the

stereochemical control by the auxiliary ring substituent. Entry 2 demonstrated the feasibility of enantioselective synthesis of α -aryl acetic acids such as the structure found in naproxen. Entries 3 to 6 include ester groups in the alkylating agent. In the case of Entry 4, it was shown that inversion occurs in the alkylating reagent. Entry 7 is an example of the use of one of the more highly substituted oxazolidinone derivatives. Entries 8 and 9 are from the synthesis of a neurotoxin isolated from a saltwater bacterium. The pseudoephedrine auxiliary shown in Entry 8 was used early in the synthesis and the 4-phenyloxazolidinone auxiliary was used later, as shown in Entry 9.

The facial selectivity of a number of more specialized enolates has also been explored, sometimes with surprising results. Schultz and co-workers compared the cyclic enolate **H** with **I**.⁹⁹ Enolate **H** presents a fairly straightforward picture. Groups such as methyl, allyl, and benzyl all give selective β -alkylation, and this is attributed to steric factors. Enolate **I** can give either α - or β -alkylation, depending on the conditions. The presence of NH_3 or use of LDA favors α -alkylation, whereas the use

⁹⁹ A. G. Schultz, M. Macielag, P. Sudararaman, A. G. Taveras, and M. Welch, *J. Am. Chem. Soc.*, **110**, 7828 (1988).

of *n*-butyllithium as the base favors β -alkylation. Other changes in conditions also affect the stereoselectivity. This is believed to be due to alternative aggregated forms of the enolate.

The compact bicyclic lactams **15** and **16** are examples of chiral systems that show high facial selectivity. Interestingly, **15** is alkylated from the convex face. When two successive alkylations are done, both groups are added from the *endo* face, so the configuration of the newly formed quaternary center can be controlled. The closely related **16** shows *exo* stereoselectivity.¹⁰⁰

Crystal structure determination and computational studies indicate substantial pyramidalization of both enolates with the higher HOMO density being on the *endo* face for both **15** and **16**. However, the TS energy [MP3/6-31G+(*d*)] correlates with experiment, favoring the *endo* TS for **15** (by 1.3 kcal/mol) and *exo* for **16** (by 0.9 kcal/mol). A B3LYP/6-31G(*d*) computational study has also addressed the stereoselectivity of **16**.¹⁰¹ As with the *ab initio* calculation, the Li⁺ is found in the *endo* position with an association with the heterocyclic oxygen. The *exo* TS is favored but the energy difference is very sensitive to the solvent model. The differences between the two systems seems to be due to the *endo* C(4) hydrogen that is present in **16** but not in **15**.

1.3. The Nitrogen Analogs of Enols and Enolates: Enamines and Imine Anions

The nitrogen analogs of ketones and aldehydes are called imines, azomethines, or Schiff bases, but *imine* is the preferred name and we use it here. These compounds can be prepared by condensation of primary amines with ketones or aldehydes.¹⁰² The equilibrium constants are unfavorable, so the reaction is usually driven forward by removal of water.

When secondary amines are heated with ketones or aldehydes in the presence of an acidic catalyst, a related reaction occurs, and the product is a substituted vinylamine or *enamine*.

There are other methods for preparing enamines from ketones that utilize strong chemical dehydrating reagents. For example, mixing carbonyl compounds and secondary amines followed by addition of titanium tetrachloride rapidly gives enamines. This method is especially applicable to hindered amines.¹⁰³ Triethoxysilane can also be used.¹⁰⁴ Another procedure involves converting the secondary amine to its *N*-trimethylsilyl derivative. Owing to the higher affinity of silicon for oxygen than nitrogen, enamine formation is favored and takes place under mild conditions.¹⁰⁵

The β -carbon atom of an enamine is a nucleophilic site because of conjugation with the nitrogen atom. Protonation of enamines takes place at the β -carbon, giving an iminium ion.

¹⁰². For general reviews of imines and enamines, see P. Y. Sollenberger and R. B. Martin, in *Chemistry of the Amino Group*, S. Patai, ed., Interscience, New York, 1968, Chap. 7; G. Pitacco and E. Valentin, in *Chemistry of Amino, Nitroso and Nitro Groups and Their Derivatives*, Part 1, S. Patai, ed., Interscience, New York, 1982, Chap. 15; P. W. The nucleophilicity of the β -carbon atoms permits enamines to be used synthetically for alkylation reactions.

The enamines derived from cyclohexanones are of particular interest. The pyrrolidine enamine is most frequently used for synthetic applications. The enamine mixture formed from pyrrolidine and 2-methylcyclohexanone is predominantly isomer **17**.¹⁰⁶ A steric effect is responsible for this preference. Conjugation between the nitrogen atom and the π orbitals of the double bond favors coplanarity of the bonds that are darkened in the structures. In isomer **17** the methyl group adopts a quasi-axial conformation to avoid steric interaction with the amine substituents.¹⁰⁷ A serious nonbonded repulsion ($A^{1,3}$ strain) in **18** destabilizes this isomer.

Owing to the predominance of the less-substituted enamine, alkylations occur primarily at the less-substituted α -carbon. Synthetic advantage can be taken of this selectivity to prepare 2,6-disubstituted cyclohexanones. The iminium ions resulting from C-alkylation are hydrolyzed in the workup procedure.

Ref. 108

Alkylation of enamines requires relatively reactive alkylating agents for good results. Methyl iodide, allyl and benzyl halides, α -halo esters, α -halo ethers, and α -halo ketones are the most successful alkylating agents. The use of enamines for selective alkylation has largely been supplanted by the methods for kinetic enolate formation described in Section 1.2.

Some enamine alkylation reactions are shown in Scheme 1.10. Entries 1 and 2 are typical alkylations using reactive halides. In Entries 3 and 4, the halides are secondary with α -carbonyl substituents. Entry 5 involves an unactivated primary bromide and the yield is modest. The reaction in Entry 6 involves introduction of two groups. This

was done by carrying out the reaction in the presence of an amine, which deprotonates the iminium ion and permits the second alkylation to occur.

Imines can be deprotonated at the α -carbon by strong bases to give the nitrogen analogs of enolates. Originally, Grignard reagents were used for deprotonation but lithium amides are now usually employed. These anions, referred to as *imine anions*

Fig. 1.6. Crystal structure of dimer of lithium salt of *N*-phenylimine of methyl *t*-butyl ketone. Two molecules of diethyl ether are present. Reproduced from *J. Am. Chem. Soc.*, **108**, 2462 (1986), by permission of the American Chemical Society.

or *metalloenamines*,¹⁰⁹ are isoelectronic and structurally analogous to both enolates and allyl anions; they can also be called *azaallyl anions*.

Spectroscopic investigations of the lithium derivatives of cyclohexanone *N*-phenylimine indicate that it exists as a dimer in toluene and that as a better donor solvent, THF, is added, equilibrium with a monomeric structure is established. The monomer is favored at high THF concentrations.¹¹⁰ A crystal structure determination was done on the lithiated *N*-phenylimine of methyl *t*-butyl ketone, and it was found to be a dimeric structure with the lithium cation positioned above the nitrogen and closer to the phenyl ring than to the β -carbon of the imine anion.¹¹¹ The structure, which indicates substantial ionic character, is shown in Figure 1.6.

Just as enamines are more nucleophilic than enol ethers, imine anions are more nucleophilic than enolates and react efficiently with alkyl halides. One application of imine anions is for the alkylation of aldehydes.

Ref. 112

Ref. 113

Ketone imine anions can also be alkylated. The prediction of the regioselectivity of lithioenamine formation is somewhat more complex than for the case of kinetic ketone enolate formation. One of the complicating factors is that there are two imine stereoisomers, each of which can give rise to two regioisomeric imine anions. The isomers in which the nitrogen substituent R' is *syn* to the double bond are the more stable.¹¹⁴

For methyl ketimines good regiochemical control in favor of methyl deprotonation, regardless of imine stereochemistry, is observed using LDA at -78°C . With larger *N*-substituents, deprotonation at 25°C occurs *anti* to the nitrogen substituent.¹¹⁵

The thermodynamic composition is established by allowing the lithiated ketimines to come to room temperature. The most stable structures are those shown below, and each case represents the less-substituted isomer.

The complete interpretation of regiochemistry and stereochemistry of imine deprotonation also requires consideration of the state of aggregation and solvation of the base.¹¹⁶

A thorough study of the factors affecting the rates of formation of lithiated imines from cyclohexanone imines has been carried out.¹¹⁷ Lithiation occurs preferentially *anti* to the *N*-substituent and with a preference for abstraction of an axial hydrogen.

If the amine carries a chelating substituent, as for 2-methoxyethylamine, the rate of deprotonation is accelerated. For any specific imine, ring substituents also influence the imine conformation and rate of deprotonation. These relationships reflect steric, stereoelectronic, and chelation influences, and sorting out each contribution can be challenging.

One of the potentially most useful aspects of the imine anions is that they can be prepared from enantiomerically pure amines. When imines derived from chiral amines are alkylated, the new carbon-carbon bond is formed with a bias for one of the two possible stereochemical configurations. Hydrolysis of the imine then leads to enantiomerically enriched ketone. Table 1.4 lists some examples that have been reported.¹¹⁸

The interpretation and prediction of the relationship between the configuration of the newly formed chiral center and the configuration of the amine is usually based on steric differentiation of the two faces of the imine anion. Most imine anions that show high stereoselectivity incorporate a substituent that can engage the metal cation in a

compact TS by chelation. In the case of Entry 2 in Table 1.4, for example, the TS **J** rationalizes the observed enantioselectivity.

The important features of this transition structure are: (1) the chelation of the methoxy group with the lithium ion, which establishes a rigid structure; (2) the interaction of the lithium ion with the bromide leaving group, and (3) the steric effect of the benzyl group, which makes the underside the preferred direction of approach for the alkylating agent.

Hydrazones can also be deprotonated to give lithium salts that are reactive toward alkylation at the β -carbon. Hydrazones are more stable than alkyimines and therefore have some advantages in synthesis.¹¹⁹ The *N,N*-dimethylhydrazones of methyl ketones are kinetically deprotonated at the methyl group. This regioselectivity is independent

¹¹⁹ D. Enders, in *Asymmetric Synthesis*, J. D. Morrison, ed., Academic Press, Orlando, FL, 1984.

of the stereochemistry of the hydrazone.¹²⁰ Two successive alkylations of the *N,N*-dimethylhydrazone of acetone provides unsymmetrical ketones.

Ref. 121

The anion of cyclohexanone *N,N*-dimethylhydrazone shows a strong preference for axial alkylation.¹²² 2-Methylcyclohexanone *N,N*-dimethylhydrazone is alkylated by methyl iodide to give *cis*-2,6-dimethylcyclohexanone. The 2-methyl group in the hydrazone occupies a pseudoaxial orientation. Alkylation apparently occurs *anti* to the lithium cation, which is on the face opposite the 2-methyl substituent.

The *N,N*-dimethylhydrazones of α,β -unsaturated aldehydes give α -alkylation, similarly to the enolates of enones.¹²³

Chiral hydrazones have also been developed for enantioselective alkylation of ketones. The hydrazones are converted to the lithium salt, alkylated, and then hydrolyzed to give alkylated ketone in good chemical yield and with high diastereoselective¹²⁴ (see Table 1.4, Entry 4). Several procedures have been developed for conversion of the hydrazones back to ketones.¹²⁵ Mild conditions are necessary to maintain the configuration at the enolizable position adjacent to the carbonyl group. The most frequently used hydrazones are those derived from *N*-amino-2-methoxymethylpyrrolidine, known as SAMP. The (*R*)-enantiomer is called RAMP. The crystal structure of the lithium anion of the SAMP hydrazone from 2-acetylnaphthalene has been determined¹²⁶ (Figure 1.7). The lithium cation is chelated by the exocyclic nitrogen and the methoxy group.

Reactions of Carbon Nucleophiles with Carbonyl Compounds

Introduction

The reactions described in this chapter include some of the most useful methods for carbon-carbon bond formation: *the aldol reaction*, the *Robinson annulation*, the *Claisen condensation* and other *carbon acylation* methods, and the *Wittig reaction* and other *olefination methods*. All of these reactions begin with the addition of a stabilized carbon nucleophile to a carbonyl group. The product that is isolated depends on the nature of the stabilizing substituent (**Z**) on the carbon nucleophile, the substituents (**A** and **B**) at the carbonyl group, and the ways in which **A**, **B**, and **Z** interact to complete the reaction pathway from the addition intermediate to the product. Four fundamental processes are outlined below. Aldol addition and condensation lead to β -hydroxyalkyl or α -alkylidene derivatives of the carbon nucleophile (Pathway **A**). The acylation reactions follow Pathway **B**, in which a group leaves from the carbonyl electrophile. In the Wittig and related olefination reactions, the oxygen in the adduct reacts with the group **Z** to give an elimination product (Pathway **C**). Finally, if the enolate has an α -substituent that is a leaving group, cyclization can occur, as in Pathway **D**. This is observed, for example, with enolates of α -haloesters. The fundamental mechanistic concepts underlying these reactions were introduced in Chapter 7 of Part A. Here we emphasize the scope, stereochemistry, and synthetic utility of these reactions.

A second important reaction type considered in this chapter is *conjugate addition*, which involves addition of nucleophiles to electrophilic double or triple bonds. A crucial requirement for this reaction is an electron-withdrawing group (EWG) that can stabilize the negative charge on the intermediate. We focus on reactions between enolates and α,β -unsaturated carbonyl compounds and other electrophilic alkenes such as nitroalkenes.

The retrosynthetic dissection is at a bond that is α to a carbonyl and β to an anion-stabilizing group.

2.1. Aldol Addition and Condensation Reactions

2.1.1. The General Mechanism

The general mechanistic features of the aldol addition and condensation reactions of aldehydes and ketones were discussed in Section 7.7 of Part A, where these general mechanisms can be reviewed. That mechanistic discussion pertains to reactions occurring in *hydroxylic solvents* and under *thermodynamic control*. These conditions are useful for the preparation of aldehyde dimers (aldols) and certain α,β -unsaturated aldehydes and ketones. For example, the mixed condensation of aromatic aldehydes with aliphatic aldehydes and ketones is often done under these conditions. The conjugation in the β -aryl enones provides a driving force for the elimination step.

The aldol reaction is also important in the synthesis of more complex molecules and in these cases control of both regiochemistry and stereochemistry is required. In most cases, this is accomplished under conditions of *kinetic control*. In the sections that follow, we discuss how variations of the basic mechanism and selection of specific reagents and reaction conditions can be used to control product structure and stereochemistry.

The addition reaction of enolates and enols with carbonyl compounds is of broad scope and of great synthetic importance. Essentially all of the stabilized carbanions mentioned in Section 1.1 are capable of adding to carbonyl groups, in what is known as the *generalized aldol reaction*. Enolates of aldehydes, ketones, esters, and amides, the carbanions of nitriles and nitro compounds, as well as phosphorus- and sulfur-stabilized carbanions and ylides undergo this reaction. In the next section we emphasize the fundamental regiochemical and stereochemical aspects of the reactions of ketones and aldehydes.

2.1.2. Control of Regio- and Stereoselectivity of Aldol Reactions of Aldehydes and Ketones

The synthetic utility of the aldol reaction depends on both the versatility of the reactants and the control of the regio- and stereochemistry. The term *directed aldol addition* is applied to reactions that are designed to achieve specific regio- and stereochemical outcomes.¹ Control of product structure requires that one reactant act exclusively as the *nucleophile* and the other exclusively as the *electrophile*. This requirement can be met by preforming the nucleophilic enolate by deprotonation, as described in Section 1.1. The enolate that is to serve as the nucleophile is generated stoichiometrically, usually with lithium as the counterion in an aprotic solvent at low temperature. Under these conditions, the kinetic enolate does not equilibrate with the other regio- or stereoisomeric enolates that can be formed from the ketone. The enolate gives a specific adduct, provided that the addition step is fast relative to proton exchange between the nucleophilic and electrophilic reactants. The reaction is under *kinetic control*, at both the stage of formation of the enolate and the addition step.

Under other reaction conditions, the product can result from *thermodynamic control*. Aldol reactions can be effected for many compounds using less than a stoichiometric amount of base. In these circumstances, the aldol reaction is reversible and the product ratio is determined by the relative stability of the various possible products. Thermodynamic conditions also permit equilibration among the enolates of the nucleophile. The conditions that lead to equilibration include higher reaction temperatures, protic or polar dissociating solvents, and the use of weakly coordinating cations. Thermodynamic conditions can be used to enrich the composition in the *most stable* of the isomeric products.

Reaction conditions that involve other enolate derivatives as nucleophiles have been developed, including boron enolates and enolates with titanium, tin, or zirconium as the metal. These systems are discussed in detail in the sections that follow, and in Section 2.1.2.5, we discuss reactions that involve *covalent enolate equivalents*, particularly silyl enol ethers. Scheme 2.1 illustrates some of the procedures that have been developed. A variety of carbon nucleophiles are represented in Scheme 2.1, including lithium and boron enolates, as well as titanium and tin derivatives, but in

each case the electrophile is an aldehyde. Pay particular attention to the retrosynthetic relationship between the products and the reactants, which corresponds in each case to Path A (p. 64). We see that the aldol addition reaction provides β -hydroxy carbonyl compounds or, more generally, adducts with a hydroxy group β to the stabilizing group Z of the carbon nucleophile.

Note also the stereochemistry. In some cases, two new stereogenic centers are formed. The hydroxyl group and any C(2) substituent on the enolate can be in a *syn* or *anti* relationship. For many aldol addition reactions, the stereochemical outcome of the reaction can be predicted and analyzed on the basis of the detailed mechanism of the reaction. Entry 1 is a mixed ketone-aldehyde aldol addition carried out by kinetic formation of the less-substituted ketone enolate. Entries 2 to 4 are similar reactions but with more highly substituted reactants. Entries 5 and 6 involve boron enolates, which are discussed in Section 2.1.2.2. Entry 7 shows the formation of a boron enolate of an amide; reactions of this type are considered in Section 2.1.3. Entries 8 to 10 show titanium, tin, and zirconium enolates and are discussed in Section 2.1.2.3.

2.1.2.1. Aldol Reactions of Lithium Enolates. Entries 1 to 4 in Scheme 2.1 represent cases in which the nucleophilic component is a lithium enolate formed by kinetically controlled deprotonation, as discussed in Section 1.1. Lithium enolates are usually highly reactive toward aldehydes and addition occurs rapidly when the aldehyde is added, even at low temperature. The low temperature ensures kinetic control and enhances selectivity. When the addition step is complete, the reaction is stopped by neutralization and the product is isolated.

The fundamental mechanistic concept for diastereoselectivity of aldol reactions of lithium enolates is based on a cyclic TS in which both the carbonyl and enolate oxygen are coordinated to the lithium cation.² The Lewis acid character of the lithium ion promotes reaction by increasing the carbonyl group electrophilicity and by bringing the reactants together in the TS. Other metal cations and electrophilic atoms can play the role of the Lewis acid, as we will see when we discuss reactions of boron and other metal enolates. The fundamental concept is that the aldol addition normally occurs through a chairlike TS. It is assumed that the structure of the TS is sufficiently similar to a chair cyclohexane that the conformational concepts developed for cyclohexane rings can be applied. In the structures that follow, the reacting aldehyde is shown with R rather than H in the equatorial-like position, which avoids a 1,3-diaxial interaction with the enolate C(1) substituent. A consequence of this mechanism is that the reaction

². (a) H. E. Zimmerman and M. D. Traxler, *J. Am. Chem. Soc.*, **79**, 1920 (1957); (b) P. Fellman and J. E. Dubois, *Tetrahedron*, **34**, 1349 (1978); (c) C. H. Heathcock, C. T. Buse, W. A. Kleschick, M. C. Pirrung, J. E. Sohn, and J. Lampe, *J. Org. Chem.*, **45**, 1066 (1980).

The preference for chairlike TSs has been confirmed by using deuterium-labeled enolates prepared from the corresponding silyl enol ethers. The ratio of the location of the deuterium corresponds closely to the ratio of the stereoisomeric enolates for several aldehydes.⁴

Provided that the reaction occurs through a chairlike TS, the $E \rightarrow anti/Z \rightarrow syn$ relationship will hold. There are three cases that can lead to departure from this relationship. These include a nonchair TS, that can involve either an open TS or a nonchair cyclic TS. Internal chelation of the aldehyde or enolate can also cause a change in TS structure.

The first element of stereocontrol in aldol addition reactions of ketone enolates is the enolate structure. Most enolates can exist as two stereoisomers. In Section 1.1.2, we discussed the factors that influence enolate composition. The enolate formed from 2,2-dimethyl-3-pentanone under kinetically controlled conditions is the *Z*-isomer.⁵ When it reacts with benzaldehyde only the *syn* aldol is formed.⁴ The product stereochemistry is correctly predicted if the TS has a conformation with the phenyl substituent in an equatorial position.

3. For consistency in designating the relative configuration the carbonyl group is numbered (1). The newly formed bond is labeled 2,3- and successive carbons are numbered accordingly. The carbons derived from the enolate are numbered 2',3', etc., starting with the α' -carbon.
4. C. M. Liu, W. J. Smith, III, D. J. Gustin, and W. R. Roush, *J. Am. Chem. Soc.*, **127**, 5770 (2005).
5. To avoid potential uncertainties in the application of the Cahn-Ingold-Prelog priority rules, by convention the enolate oxygen is assigned the higher priority.

A similar preference for formation of the *syn* aldol is found for other Z-enolates derived from ketones in which one of the carbonyl substituents is bulky. Ketone enolates with less bulky substituents show a decreasing stereoselectivity in the order *t*-butyl > *i*-propyl > ethyl.^{2c} This trend parallels a decreasing preference for stereoselective formation of the Z-enolate.

The enolates derived from cyclic ketones are necessarily *E*-isomers. The enolate of cyclohexanone reacts with benzaldehyde to give both possible stereoisomeric products. The stereoselectivity is about 5:1 in favor of the *anti* isomer under optimum conditions.⁶

From these and many related examples the following generalizations can be made about kinetic stereoselection in aldol additions of lithium enolates. (1) The chair TS model provides a basis for analyzing the stereoselectivity observed in aldol reactions of ketone enolates having one bulky substituent. The preference is *Z*-enolate \rightarrow *syn* aldol; *E*-enolate \rightarrow *anti* aldol. (2) When the enolate has no bulky substituent, stereoselectivity is low. (3) *Z*-Enolates are more stereoselective than *E*-enolates. Table 2.1 gives some illustrative data.

The requirement that an enolate have at least one bulky substituent restricts the types of compounds that give highly stereoselective aldol additions via the lithium enolate method. Furthermore, only the enolate formed by kinetic deprotonation is directly available. Whereas ketones with one tertiary alkyl substituent give mainly the *Z*-enolate, less highly substituted ketones usually give mixtures of *E*- and *Z*-enolates.⁷ (Review the data in Scheme 1.1.) Therefore efforts aimed at increasing the stereoselectivity of aldol additions have been directed at two facets of the problem: (1) better control of enolate stereochemistry, and (2) enhancement of the degree of stereoselectivity in the addition step, which is discussed in Section 2.1.2.2.

The *E*:*Z* ratio can be modified by the precise conditions for formation of the enolate. For example, the *E*:*Z* ratio for 3-pentanone and 2-methyl-3-pentanone can be increased by use of a 1:1 lithium tetramethylpiperidide(LiTMP)-LiBr mixture for

kinetic enolization.⁸ The precise mechanism of this effect is still a matter of investigation, but it is probably due to an aggregate species containing bromide acting as the base (see Section 1.1.1).⁹

	<i>E:Z</i> Stereoselectivity		
	LDA	LiTMP	LiTMP + LiBr
$\text{CH}_3\text{CH}_2\overset{\text{O}}{\parallel}\text{CCH}_2\text{CH}_3$	3.3:1	5:1	50:1
$(\text{CH}_3)_2\text{CH}\overset{\text{O}}{\parallel}\text{CCH}_2\text{CH}_3$	1.7:1	2:1	21:1
$(\text{CH}_3)_3\text{C}\overset{\text{O}}{\parallel}\text{CCH}_2\text{CH}_3$	1: >50	1: >20	1: >20

Other changes in deprotonation conditions can influence enolate composition. Relatively weakly basic lithium anilides, specifically lithium 2,4,6-trichloroanilide and lithium diphenylamide, give high *Z:E* ratios.¹⁰ Lithio 1,1,3,3-tetramethyl-1,3-diphenyldisilylamide is also reported to favor the *Z*-enolate.¹¹ On the other hand, lithium *N*-trimethylsilyl-*iso*-propylamide and lithium *N*-trimethylsilyl-*tert*-butylamide give selectivity for the *E*-enolate¹² (see Scheme 1.1).

When aldol addition is carried out under thermodynamic conditions, the product stereoselectivity is usually not as high as under kinetic conditions. All the regio- and stereoisomeric enolates can participate as nucleophiles. The adducts can return to reactants, so the difference in *stability* of the stereoisomeric *anti* and *syn* products determines the product composition. In the case of lithium enolates, the adducts can be equilibrated by keeping the reaction mixture at room temperature. This has been done, for example, with the product from the reaction of the enolate of 2,2-dimethyl-3-pentanone and benzaldehyde. The greater stability of the *anti* isomer is attributed to the pseudoequatorial position of the methyl group in the chairlike product chelate. With larger substituent groups, the thermodynamic preference for the *anti* isomer is still greater.¹³

For synthetic efficiency, it is useful to add MgBr₂, which accelerates the equilibration.

Ref. 14

2.1.2.2. Aldol Reactions of Boron Enolates. The matter of increasing stereoselectivity in the addition step can be addressed by using other reactants. One important version of the aldol reaction involves the use of boron enolates.¹⁵ A cyclic TS similar to that for lithium enolates is involved, and the same relationship exists between enolate configuration and product stereochemistry. In general, the stereoselectivity is higher than for lithium enolates. The O–B bond distances are shorter than for lithium enolates, and this leads to a more compact structure for the TS and magnifies the steric interactions that control stereoselectivity.

Boron enolates can be prepared by reaction of the ketone with a dialkylboron trifluoromethanesulfonate (triflate) and a tertiary amine.¹⁶ Use of boron triflates and a bulky amine favors the *Z*-enolate. The resulting aldol products are predominantly the *syn* stereoisomers.

The *E*-boron enolates of some ketones can be preferentially obtained by using dialkylboron chlorides.¹⁷

The contrasting stereoselectivity of the boron triflates and chlorides has been discussed in terms of reactant conformation and the stereoelectronic requirement for perpendicular alignment of the hydrogen being removed with the carbonyl group π orbital.¹⁸ With the triflate reagents, the boron is *anti* to the enolizable group. With the bulkier dicyclohexylboron chloride, the boron favors a conformation *cis* to the enolizable group. A computational study of the reaction also indicates that the size of the boron ligand and the resulting conformational changes are the dominant factors in determining stereoselectivity.¹⁹ There may also be a distinction between the two types of borylation reagents in the extent of dissociation of the leaving group. The triflate is probably an ion pair, whereas with the less reactive chloride, the deprotonation may be a concerted ($\text{E}2$ -like) process.^{18b} The two proposed TSs are shown below.

Z-Boron enolates can also be obtained from silyl enol ethers by reaction with the bromoborane derived from 9-BBN (9-borabicyclo[3.3.1]nonane). This method is necessary for ketones such as 2,2-dimethyl-3-pentanone, which give *E*-boron enolates by other methods. The *Z*-stereoisomer is formed from either the *Z*- or *E*-silyl enol ether.²⁰

The *E*-boron enolate from cyclohexanone shows a preference for the *anti* aldol product. The ratio depends on the boron alkyl groups and is modest (2:1) with di-*n*-butylboron but greater than 20:1 for cyclopentyl-*n*-hexylboron.¹⁶

The general trend is that boron enolates *parallel* lithium enolates in their stereoselectivity but show *enhanced stereoselectivity*. There also are some advantages in terms of access to both stereoisomeric enol derivatives. Another important characteristic of boron enolates is that they are not subject to internal chelation. The tetracoordinate dialkylboron in the cyclic TS is not able to accept additional ligands, so there is no tendency to form a chelated TS when the aldehyde or enolate carries a donor substituent. Table 2.2 gives some typical data for boron enolates and shows the strong correspondence between enolate configuration and product stereochemistry.

2.1.2.3. Aldol Reactions of Titanium, Tin, and Zirconium Enolates. Metals such as Ti, Sn, and Zr give enolates that are intermediate in character between the ionic Li⁺ enolates and covalent boron enolates. The Ti, Sn, or Zr enolates can accommodate additional ligands. Tetra-, penta-, and hexacoordinate structures are possible. This permits the formation of chelated TSs when there are nearby donor groups in the enolate or electrophile. If the number of anionic ligands exceeds the oxidation state of the metal, the complex has a formal negative charge on the metal and is called an “ate” complex. Such structures enhance the nucleophilicity of enolate ligands. Depending on the nature of the metal ligands, either a cyclic or an acyclic TS can be involved. As we will see in Section 2.1.3.5, the variability in the degree and nature of coordination provides an additional factor in analysis and control of stereoselectivity.

Titanium enolates can be prepared from lithium enolates by reaction with a trialkoxy-titanium(IV)chloride, such as *tris*-(isopropoxy)titanium chloride.²¹ Titanium enolates are usually prepared directly from ketones by reaction with TiCl₄ and a tertiary amine.²² Under these conditions, the *Z*-enolate is formed and the aldol adducts have *syn* stereochemistry. The addition step proceeds through a cyclic TS assembled around titanium.

Entry 8 in Scheme 2.1 is an example of this method. Titanium enolates are frequently employed in the synthesis of complex molecules and with other carbonyl derivatives,

²¹ C. Siegel and E. R. Thornton, *J. Am. Chem. Soc.*, **111**, 5722 (1989).

such as the *N*-acyloxazolidinones that serve as chiral auxiliaries (see Section 2.1.3.4).

Mixed aldehyde-aldehyde additions have been carried out using TiCl_4 and TMEDA. The reaction gives *syn* adducts, presumably through a cyclic TS. Treatment of the *syn* adducts with 1 mol % $\text{Ti}(\text{O-}i\text{-Pr})_4$ leads to equilibration to the more stable *anti* isomer.²³

The equilibration in this case is believed to involve oxidation-reduction at the alcohol center, rather than reversal of the addition. (See Section 5.3.2 for a discussion of $\text{Ti}(\text{O-}i\text{-Pr})_4$ as an oxidation-reduction catalyst.)

Ketone-aldehyde additions have been effected using TiCl_4 in toluene.²⁴ These reactions exhibit the same stereoselectivity trends as other titanium-mediated additions. With unsymmetrical ketones, this procedure gives the product from the more-substituted enolate.²⁵

Titanium enolates can also be used under conditions in which the titanium exists as an “ate” species. Crossed aldehyde-aldehyde additions have been accomplished starting with trimethylsilyl enol ethers, which are converted to lithium enolates and then to “ate” species by addition of $\text{Ti}(\text{O-}n\text{-Bu})_4$.²⁶ These conditions show only modest stereoselectivity.

Titanium “ate” species have also been used to add aldehyde enolates to ketones. This reaction is inherently difficult because of the greater reactivity of aldehyde

carbonyls over ketone carbonyls. The reaction works best with ketones having EWG substituents such as alkynones and α -haloketones. The reaction is thought to proceed through a cyclic intermediate that is stable until hydrolysis. This cyclic intermediate may be necessary to drive the normally unfavorable equilibrium of the addition step.

Tin enolates are also used in aldol reactions.²⁷ Both the Sn(II) and Sn(IV) oxidation states are reactive. Tin(II) enolates can be generated from ketones and $\text{Sn(II)(O}_3\text{SCF}_3)_2$ in the presence of tertiary amines.²⁸ The subsequent aldol addition is *syn* selective and independent of enolate configuration.²⁹ This preference arises from avoidance of *gauche* interaction of the aldehyde group and the enolate β -substituent. The *syn* stereoselectivity indicates that reaction occurs through an open TS.

Even cyclohexanone gives the *syn* product.

Entry 9 of Scheme 2.1 is an example of application of these conditions. Tin(II) enolates prepared in this way also show good reactivity toward ketones as the electrophilic component.

Trialkylstannyl enolates can be prepared from enol acetates by reaction with trialkyltin alkoxides and are sufficiently reactive to add to aldehydes. Uncatalyzed addition of trialkylstannyl enolates to benzaldehyde shows *anti* stereoselectivity.³¹

Isolated tri-*n*-butylstannyl enolates react with benzaldehyde under the influence of metal salts including $\text{Pd}(\text{O}_3\text{SCF}_3)_2$, $\text{Zn}(\text{O}_3\text{SCF}_3)_2$, and $\text{Cu}(\text{O}_3\text{SCF}_3)_2$.³² The tri-*n*-butylstannyl enol derivative of cyclohexanone gives mainly *anti* product. The *anti:syn* ratio depends on the catalyst, with $\text{Pd}(\text{O}_3\text{SCF}_3)_2$ giving the highest ratio.

Zirconium *tetra-t*-butoxide is a mildly basic reagent that has occasionally been used to effect aldol addition.³³

Zirconium enolates can also be prepared by reaction of lithium enolates with $(\text{Cp})_2\text{ZrCl}_2$, and they act as nucleophiles in aldol addition reactions.³⁴

A comparison of the *anti:syn* diastereoselectivity of the lithium, dibutylboron, and (Cp)₂Zr enolates of 3-methyl-2-hexanone with benzaldehyde has been reported.^{34d} The order of stereoselectivity is Bu₂B > (Cp)₂Zr > Li. These results suggest that the reactions of the zirconium enolates proceed through a cyclic TS.

2.1.2.4. Summary of the Relationship between Diastereoselectivity and the Transition Structure. In this section we considered *simple diastereoselection* in aldol reactions of ketone enolates. Numerous observations on the reactions of enolates of ketones and related compounds are consistent with the general concept of a chairlike TS.³⁵ These reactions show a consistent *E* → *anti* : *Z* → *syn* relationship. Noncyclic TSs have more variable diastereoselectivity. The prediction or interpretation of the specific ratio of *syn* and *anti* product from any given reaction requires assessment of several variables: (1) What is the stereochemical composition of the enolate? (2) Does the Lewis acid promote tight coordination with both the carbonyl and enolate oxygen atoms and thereby favor a cyclic TS? (3) Does the TS have a chairlike conformation? (4) Are there additional Lewis base coordination sites in either reactant that can lead to reaction through a chelated TS? Another factor comes into play if either the aldehyde or the enolate, or both, are chiral. In that case, facial selectivity becomes an issue and this is considered in Section 2.1.5.

2.1.3. Aldol Addition Reactions of Enolates of Esters and Other Carbonyl Derivatives

The enolates of other carbonyl compounds can be used in mixed aldol reactions. Extensive use has been made of the enolates of esters, thiol esters, amides, and imides, including several that serve as chiral auxiliaries. The methods for formation of these enolates are similar to those for ketones. Lithium, boron, titanium, and tin derivatives have all been widely used. The silyl ethers of ester enolates, which are called *silyl ketene acetals*, show reactivity that is analogous to silyl enol ethers and are covalent equivalents of ester enolates. The silyl thioketene acetal derivatives of thiol esters are also useful. The reactions of these enolate equivalents are discussed in Section 2.1.4.

Because of their usefulness in aldol additions and other synthetic methods (see especially Section 6.4.2.3), there has been a good deal of interest in the factors that

control the stereoselectivity of enolate formation from esters. For simple esters such as ethyl propanoate, the *E*-enolate is preferred under kinetic conditions using a strong base such as LDA in THF solution. Inclusion of a strong cation-solvating cosolvent, such as HMPA or DMPU, favors the *Z*-enolate.³⁶ These enolates can be trapped and analyzed as the corresponding silyl ketene acetals. The relationships are similar to those discussed for formation of ketone enolates in Section 1.1.2.

These observations are explained in terms of a chairlike TS for the LDA/THF conditions and a more open TS in the presence of an aprotic dipolar solvent.

Despite the ability to control ester enolate geometry, the aldol addition reactions of unhindered ester enolate are not very stereoselective.³⁷

This stereoselectivity can be improved by use of a very bulky group. 2,6-Dimethylphenyl esters give *E*-enolates and *anti* aldol adducts.³⁸

The lithium enolates of α -alkoxy esters exhibit high stereoselectivity, which is consistent with involvement of a chelated enolate.^{37a,39} The chelated ester enolate is approached by the aldehyde in such a manner that the aldehyde R group avoids being between the α -alkoxy and methyl groups in the ester enolate. A *syn* product is favored for most ester groups, but this shifts to *anti* with extremely bulky groups.

Boron enolates can be obtained from esters^{40,41} and amides⁴² by methods that are similar to those used for ketones. Various combinations of borylating reagents and amines have been used and the *E:Z* ratios are dependent on the reagents and conditions. In most cases esters give *Z*-enolates, which lead to *syn* adducts, but there are exceptions. Use of branched-chain alcohols increases the amount of *anti* enolate, and with *t*-butyl esters the product ratio is higher than 97:3.

⁴². K. Ganesan and H. C. Brown, *J. Org. Chem.*, **59**, 7346 (1994).

Branched-chain esters also give mainly *anti* adducts when the enolates are formed using dicyclohexylidoborane.

Phenyl and phenylthio esters have proven to be advantageous in TiCl_4 -mediated additions, perhaps because they are slightly more acidic than the alkyl analogs. The reactions show *syn* diastereoselectivity, indicating that *Z*-enolates are formed.⁴³

Among the most useful carbonyl derivatives are *N*-acyloxazolidinones, and as we shall see in Section 2.3.4, they provide facial selectivity in aldol addition reactions. 1,3-Thiazoline-2-thiones constitute another useful type of chiral auxiliary, and they can be used in conjunction with $\text{Bu}_2\text{BO}_3\text{SCF}_3$,⁴⁴ $\text{Sn}(\text{O}_3\text{SCF}_3)_2$,⁴⁵ or TiCl_4 ⁴⁶ for generation of enolates. The stereoselectivity of the reactions is consistent with formation of a *Z*-enolate and reaction through a cyclic TS.

2.1.4. The Mukaiyama Aldol Reaction

The *Mukaiyama aldol reaction* refers to Lewis acid-catalyzed aldol addition reactions of silyl enol ethers, silyl ketene acetals, and similar *enolate equivalents*.⁴⁸ Silyl enol ethers are not sufficiently nucleophilic to react directly with aldehydes or ketones. However, Lewis acids cause reaction to occur by coordination at the carbonyl oxygen, activating the carbonyl group to nucleophilic attack.

Lewis acids such as TiCl_4 and SnCl_4 induce addition of both silyl enol ethers and ketene silyl acetals to aldehydes.⁴⁹

If there is no other interaction, the reaction proceeds through an acyclic TS and steric factors determine the amount of *syn* versus *anti* addition. This is the case with BF_3 , where the tetracoordinate boron-aldehyde adduct does not offer any free coordination sites for formation of a cyclic TS. Stereoselectivity increases with the steric bulk of the silyl enol ether substituent R^1 .⁵⁰

Quite a number of other Lewis acids can catalyze the Mukaiyama aldol reaction, including $\text{Bu}_2\text{Sn}(\text{O}_3\text{SCF}_3)_2$,⁵¹ $\text{Bu}_3\text{SnClO}_4$,⁵² $\text{Sn}(\text{O}_3\text{SCF}_3)_2$,⁵³ $\text{Zn}(\text{O}_3\text{SCF}_3)_2$,⁵⁴ and

LiClO_4 .⁵⁵ Cerium, samarium, and other lanthanide halides promote addition of silyl ketene acetals to aldehydes.⁵⁶ Triaryl perchlorate salts are also very active catalysts.⁵⁷ In general terms, there are at least three possible mechanisms for catalysis. One is through Lewis acid activation of the electrophilic carbonyl component, similar to that discussed for BF_3 , TiCl_4 , and SnCl_4 . Another is by exchange with the enolate equivalent to generate a more nucleophilic species. A third is activation of a catalytic cycle that generates trimethylsilyl cation as the active catalysts.

Aldol additions of silyl enol ethers and silyl ketene acetals can be catalyzed by $(\text{Cp})_2\text{Zr}^{2+}$ species including $[(\text{Cp})_2\text{ZrO}-t\text{-Bu}]^+$ and $(\text{Cp})_2\text{Zr}(\text{O}_3\text{SCF}_3)_2$.⁵⁸

The catalytic cycle involves transfer of the silyl group to the adduct.

Trialkylsilyl cations may play a key role in other Lewis acid-catalyzed reactions.⁵⁹ For example, trimethylsilyl triflate can be formed by intermolecular transfer of the silyl group. When this occurs, the trimethylsilyl triflate can initiate a catalytic cycle that does not directly involve the Lewis acid.

Hindered *bis*-phenoxyaluminum derivatives are powerful cocatalysts for reactions mediated by TMS triflate and are believed to act by promoting formation of trimethylsilyl cations by sequestering the triflate anion.⁶⁰

MABR = *bis*-(4-bromo-2,6-di-*tert*-butylphenoxy)methylaluminum

The lanthanide salts are unique among Lewis acids in that they can be effective as catalysts in aqueous solution.⁶¹ Silyl enol ethers react with formaldehyde and benzaldehyde in water-THF mixtures using lanthanide triflates such as $\text{Yb}(\text{O}_3\text{SCF}_3)_3$. The catalysis reflects the strong affinity of lanthanides for carbonyl oxygen, even in aqueous solution.

Ref. 62

Certain other metal ions also exhibit catalysis in aqueous solution. Two important criteria are rate of ligand exchange and the acidity of the metal hydrate. Metal hydrates that are too acidic lead to hydrolysis of the silyl enol ether, whereas slow exchange limits the ability of catalysis to compete with other processes. Indium(III) chloride is a borderline catalysts by these criteria, but nevertheless is effective. The optimum solvent is 95:5 isopropanol-water. Under these conditions, the reaction is *syn* selective, suggesting a cyclic TS.⁶³

In addition to aldehydes, acetals can serve as electrophiles in Mukaiyama aldol reactions.⁶⁴ Effective catalysts include TiCl_4 ,⁶⁵ SnCl_4 ,⁶⁶ $(\text{CH}_3)_3\text{SiO}_3\text{SCF}_3$,⁶⁷ and

$\text{Bu}_2\text{Sn}(\text{O}_3\text{SCF}_3)_2$.⁶⁸ The Lewis acids promote ionization of the acetal to an oxonium ion that acts as the electrophile. The products are β -alkoxy ketones.

In some cases, the enolate can be formed directly in the presence of the acetal with the Lewis acid also activating the acetal.⁶⁹

Dibutylboron triflate promotes both enol borinate formation and addition.⁷⁰

Reactions with acetals can serve to introduce β -alkoxy groups into complex molecules, as in the following reaction.⁷¹

It has been proposed that there may be a single electron transfer mechanism for the Mukaiyama reaction under certain conditions.⁷² For example, photolysis of benzaldehyde dimethylacetal and 1-trimethylsilyloxycyclohexene in the presence of a

typical photoelectron acceptor, triphenylpyrylium cation, gives an excellent yield of the addition product.

Ref. 73

These reactions may operate by providing a source of trimethylsilyl cations, which serve as the active catalyst by a cycle similar to that for Lewis acids.

The Mukaiyama aldol reaction can provide access to a variety of β -hydroxy carbonyl compounds and use of acetals as reactants can provide β -alkoxy derivatives. The issues of stereoselectivity are the same as those in the aldol addition reaction, but the tendency toward acyclic rather than cyclic TSs reduces the influence of the *E*- or *Z*-configuration of the enolate equivalent on the stereoselectivity.

Scheme 2.2 illustrates several examples of the Mukaiyama aldol reaction. Entries 1 to 3 are cases of addition reactions with silyl enol ethers as the nucleophile and TiCl_4 as the Lewis acid. Entry 2 demonstrates steric approach control with respect to the silyl enol ether, but in this case the relative configuration of the hydroxyl group was not assigned. Entry 4 shows a fully substituted silyl enol ether. The favored product places the larger C(2) substituent *syn* to the hydroxy group. Entry 5 uses a silyl ketene thioacetal. This reaction proceeds through an open TS and favors the *anti* product.

Entries 6 to 9 involve reactions conducted under catalytic conditions. Entry 6 uses a lanthanide catalyst that is active in aqueous solution. Entries 7 and 8 are examples of the use of $(\text{Cp})_2\text{Ti}(\text{O}_3\text{SCF}_3)_2$ as a Lewis acid. Entry 9 illustrates the TMS triflate-MABR catalytic combination.

Entries 10 to 14 show reactions involving acetals. Interestingly, Entry 10 shows much-reduced stereoselectivity compared to the corresponding reaction of the aldehyde (The BF_3 -catalyzed reaction of the aldehyde is reported to be 24:1 in favor of the *anti* product; ref. 80, p. 91). There are no stereochemical issues in Entries 11 or 12. Entry 13, involving two cyclic reactants, gave a 2:1 mixture of stereoisomers. Entry 14 is a step in a synthesis directed toward the taxane group of diterpenes. Four stereoisomeric products were produced, including the *Z:E* isomers at the new enone double bond.

2.1.5. Control of Facial Selectivity in Aldol and Mukaiyama Aldol Reactions

In the discussion of the stereochemistry of aldol and Mukaiyama reactions, the most important factors in determining the *syn* or *anti* diastereoselectivity were identified as the nature of the TS (cyclic, open, or chelated) and the configuration (*E* or *Z*) of the enolate. If either the aldehyde or enolate is chiral, an additional factor enters the picture. The aldehyde or enolate then has two nonidentical faces and the stereochemical outcome will depend on *facial selectivity*. In principle, this applies to any stereocenter in the molecule, but the strongest and most studied effects are those of α - and β -substituents. If the aldehyde is chiral, particularly when the stereogenic center is adjacent to the carbonyl group, the competition between the two diastereotopic faces of the carbonyl group determines the stereochemical outcome of the reaction.

Similarly, there will be a degree of selectivity between the two faces of the enolate if it contains a stereocenter.

The stereogenic centers may be integral parts of the reactants, but chiral auxiliaries can also be used to impart facial diastereoselectivity and permit eventual isolation of enantiomerically enriched product. Alternatively, use of chiral Lewis acids as catalysts can also achieve facial selectivity. Although the general principles of control of the stereochemistry of aldol addition reactions have been well developed for simple molecules, the application of the principles to more complex molecules and the

selection of the optimum enolate system requires analyses of the individual cases.⁷⁴ Often, one of the available reactant systems proves to be superior.⁷⁵ Sometimes a remote structural feature strongly influences the stereoselectivity.⁷⁶ The issues that have to be addressed in specific cases include the structure of the reactants, including its configuration and potential sites for chelation; the organization of the TS (cyclic, open, or chelated); and the steric, electronic, and polar factors affecting the facial selectivity.

2.1.5.1. Stereochemical Control by the Aldehyde. A chiral center in an aldehyde can influence the direction of approach by an enolate or other nucleophile. This facial selectivity is in addition to the simple *syn*, *anti* diastereoselectivity so that if either the aldehyde or enolate contains a stereocenter, four stereoisomers are possible. There are four possible chairlike TSs, of which two lead to *syn* product from the *Z*-enolate and two to *anti* product from the *E*-enolate. The two members of each pair differ in the facial approach to the aldehyde and give products of opposite configuration at *both of the newly formed stereocenters*. If the substituted aldehyde is racemic, the enantiomeric products will be formed, making a total of eight stereoisomers possible.

If the substituents are nonpolar, such as an alkyl or aryl group, the control is exerted mainly by steric effects. In particular, for α -substituted aldehydes, the Felkin TS model can be taken as the starting point for analysis, in combination with the cyclic TS. (See Section 2.4.1.3, Part A to review the Felkin model.) The analysis and prediction of the direction of the preferred reaction depends on the same principles as for simple diastereoselectivity and are done by consideration of the attractive and repulsive interactions in the presumed TS. In the Felkin model for nucleophilic addition to carbonyl centers the larger α -substituent is aligned *anti* to the approaching enolate and yields the 3,4-*syn* product. If reaction occurs by an alternative approach, the stereochemistry is reversed, and this is called an anti-Felkin approach.

A study of the lithium enolate of pinacolone with several α -phenyl aldehydes gave results generally consistent with the Felkin model. Steric, rather than electronic, effects determine the conformational equilibria.⁷⁷ If the alkyl group is branched, it occupies the “large” position. Thus, the *t*-butyl group occupies the “large” position, not the phenyl.

R	3,4- <i>anti</i> : <i>syn</i> ratio
CH ₃	3.64:1
C ₂ H ₅	6.05:1
(CH ₃) ₂ CH	2.25:1
(CH ₃) ₃ C	1:1.7

The situation encounters another factor with enolates having a C(2) substituent. The case of steric control has been examined carefully. The stereoselectivity depends on the orientation of the stereocenter relative to the remainder of the TS. The Felkin TS is **A**. TS **B** represents a non-Felkin conformer, but with the same facial approach as **A**. The preferred TS for the *Z*-enolate is believed to be structure **C**. This TS is preferred to **A** because of the interaction between the R^M group and the R² group of the enolate

⁷⁷ E. P. Lodge and C. H. Heathcock, *J. Am. Chem. Soc.*, **109**, 3353 (1987).

in **A**.⁷⁸ This *double-gauche* interaction is analogous to the 1,3-diaxial relationship in chair cyclohexane. TS **C** results in the anti-Felkin approach. The relative energy of TS **B** and TS **C** depends on the size of R^L , with larger R groups favoring TS **C** because of an increased R^2/R^L interaction.

For *E*-enolates the Felkin TS is preferred, the enolate approaches opposite the largest aldehyde substituent, and the preferred product is 2,3-*anti*-3,4-*syn*. TS **D** is preferred for *E*-enolates because of the *gauche* interaction between R^2 and R^L in TS **E**.

The qualitative application of these models depends on evaluating the magnitude of the steric interactions among the various groups. In this regard, phenyl and vinyl groups seem to be smaller than alkyl groups, perhaps because of their ability to rotate into conformations in which the π dimension minimizes steric repulsions. These concepts have been quantitatively explored using force field models. For nonpolar substituents, steric interactions are the controlling factor in the stereoselectivity, but there is considerable flexibility for adjustment of the TS geometry in response to the specific interactions.⁷⁹

Mukaiyama reactions of α -methyl aldehydes proceed through an open TS and show a preference for the 3,4-*syn* stereoisomer, which is consistent with a Felkin TS.⁸⁰

The stereoselectivity of aldol addition is also affected by chelation.⁸¹ α - and β -alkoxy aldehydes can react through chelated structures with Li^+ and other Lewis acids that can accommodate two donor groups.

The potential for coordination depends on the oxy substituents.⁸² Alkoxy substituents are usually chelated, whereas highly hindered silyloxy groups usually do not chelate. Trimethylsiloxy groups are intermediate in chelating ability. The extent of chelation also depends on the Lewis acid. Studies with α -alkoxy and β -alkoxy aldehydes with lithium enolates found only modest diastereoselectivity.⁸³

Ref. 84

Ref. 83b

Several α -methyl- β -alkoxyaldehydes show a preference for 2,3-*syn*-3,4-*anti* products on reaction with *Z*-enolates. A chelated TS can account for the observed stereochemistry.⁸⁵ The chelated aldehyde is most easily approached from the face opposite the methyl and R' substituents.

Dialkylboron enolates cannot accommodate an additional aldehyde ligand group and chelated TSs are not expected. When BF_3 is used as the Lewis acid, chelation is

also precluded in Mukaiyama reactions. Chelation control does occur in the Mukaiyama reaction using other Lewis acids. Both α - and β -alkoxy aldehydes give chelation-controlled products with SnCl_4 and TiCl_4 , but not with BF_3 .⁸⁶ If there is an additional substituent on the aldehyde, the chelate establishes a facial preference for the approach of the nucleophile.⁸⁷

In each instance, the silyl enol ether approaches *anti* to the methyl substituent on the chelate. This results in a 3,4-*syn* relationship between the hydroxy and alkoxy groups for α -alkoxy aldehydes and a 3,5-*anti* relationship for β -alkoxy aldehydes with the main chain in the extended conformation.

Ref. 84

A crystal structure is available for the SnCl_4 complex of 2-benzyloxy-3-pentanone.⁸⁹ The steric shielding by the methyl group with respect to the $\text{C}=\text{O}$ is evident in this structure (Figure 2.1). NMR studies indicate that the reaction involves

formation of trimethylsilyl chloride from the chelated intermediate. This step is followed by conversion to the more stable aldol chelate.⁹⁰

With α - and β -benzyloxyaldehydes, the *t*-butylthio ketene acetals also gave chelation-controlled addition.⁹¹

This reaction occurs through a TS in which the aldehyde is chelated, but the silyl thio ketene acetal is not coordinated to the Ti (open TS).

The choice of Lewis acid can determine if a chelated or open TS is involved. For example, all four possible stereoisomers of **1** were obtained by variation of the Lewis acid and the stereochemistry in the reactant.⁹² The BF_3 -catalyzed reactions occur through an open TS, whereas the TiCl_4 reactions are chelation controlled.

In the reaction of α -methylthiobutanal, where the methylthio group has the potential for chelation, BF_3 gave 100% of *anti* product, whereas TiCl_4 gave a 5:1 *syn:anti* ratio.⁹³

Chelation-controlled product is formed from reaction of α -benzyloxypropanal and the TBDMS silyl ketene acetal derived from ethyl acetate using 3% LiClO_4 as catalyst.⁹⁴

Recently, $(\text{CH}_3)_2\text{AlCl}$ and CH_3AlCl_2 have been shown to have excellent chelation capacity. These catalysts effect chelation control with both 3-benzyloxy- and 3-(*t*-butyldimethylsilyloxy)-2-methylpropanal, whereas BF_3 leads to mainly *syn* product.⁹⁵ The reaction is believed to occur through a cationic complex, with the chloride ion associated with a second aluminum as $[(\text{CH}_3)_2\text{AlCl}_2]^-$. Interestingly, although TiCl_4 induced chelation control with the benzyloxy group, it did not do so with the TBDMS group.

Lewis acid	R = CH_2Ph	R = OTBDMS

Heteroatom substituents also introduce polar effects. In the case of α -alkoxy aldehydes the preferred TS appears to be **F** and **G** for the *E*- and *Z*-enolates, respectively. These differ from the normal Felkin TS for nucleophilic addition. The reactant conformation is believed to be determined by minimization of dipolar repulsion between the alkoxy substituent and the carbonyl group.⁹⁶ This model predicts higher 3,4-*anti* ratios for *Z*-enolates, and this is observed.

Dipole-dipole interactions may also be important in determining the stereoselectivity of Mukaiyama aldol reactions proceeding through an open TS. A BF_3 -catalyzed reaction was found to be 3,5-*anti* selective for several β -substituted 5-phenylpentanals. This result can be rationalized by a TS that avoids an unfavorable alignment of the $\text{C}=\text{O}$ and $\text{C}-\text{X}$ dipoles.⁹⁷

The same stereoselectivity was observed with a more complex pair of reactants in which the β -substituent is a cyclic siloxy oxygen.⁹⁸

Thus we see that steric effects, chelation, and the polar effects of α - and β -substituents can influence the facial selectivity in aldol additions to aldehydes. These relationships provide a starting point for prediction and analysis of stereoselectivity

based on structural effects in the reactant aldehyde. These general principles have been applied to the synthesis of a number of more complex molecules. Table 2.3 summarizes the relationships discussed in this section.

Scheme 2.3 shows reactions of several substituted aldehydes of varying complexity that illustrate aldehyde facial diastereoselectivity in the aldol and Mukaiyama reactions. The stereoselectivity of the new bond formation depends on the effect that reactant substituents have on the detailed structure of the TS. The 3,4-*syn* stereoselectivity of Entry 1 derives from a Felkin-type acyclic TS.

Entry 2 shows an *E*-enolate of a hindered ester reacting with an aldehyde having both an α -methyl and β -methoxy group. The reaction shows a 13:1 preference for the Felkin approach product (3,4-*syn*) and is controlled by the steric effect of the α -methyl substituent. Another example of steric control with an ester enolate is found in a step in the synthesis of (+)-discodermolide.⁹⁹ The *E*-enolate of a hindered aryl ester was generated using LiTMP and LiBr. Reaction through a Felkin TS resulted in *syn* diastereoselectivity for the hydroxy and ester groups at the new bond.

Entries 3 and 8 show additions of a silyl thioketene acetal to α -substituted aldehydes. Entry 3 is under steric control and gives an 13:1 2,3-*anti*:*syn* ratio. The reaction proceeds through an open TS with respect to the nucleophile and both the

E- and *Z*-silyl thioketene acetals give the 2,3-*anti* product. The 3,4-*syn* ratio is 50:1, and is consistent with the Felkin model. When this nucleophile reacts with 2-benzyloxypromanal (Entry 8), a chelation product results. The facial selectivity with respect to the methyl group is now reversed. Both isomers of the silyl thioketene acetal give mainly the 2,3-*syn*-3,4-*syn* product. The ratio is higher than 30:1 for the *Z*-enolate but only 3:1 for the *E*-enolate.

Entries 4 and 9 are closely related structures that illustrate the ability to control stereochemistry by choice of the Lewis acid. In Entry 4, the Lewis acid is BF_3 and the β -oxygen is protected as a *t*-butyldiphenylsilyl derivative. This leads to reaction through an open TS, and the reaction is under steric control, resulting in the 3,4-*syn* product. In Entry 9, the enolate is formed using di-*n*-butylboron triflate (1.2 equiv.), which permits the aldehyde to form a chelate. The chelated aldehyde then reacts via an open TS with respect to the silyl ketene acetal, and the 3,4-*anti* isomer dominates by more than 20:1.

Entry 5 is an example of LiClO_4 catalysis and results in very high stereoselectivity, consistent with a chelated structure for the aldehyde.

Entries 6 and 7 are examples of reactions of α -benzyloxypromanal. In both cases, the product stereochemistry is consistent with a chelated TS.

Entry 10 is an example of the application of chelate-controlled stereoselectivity using TiCl_4 . Entry 11 also involves stereodirection by a β -(*p*-methoxybenzyloxy) substituent. In this case, the BF_3 -catalyzed reaction should proceed through an open TS and the β -polar effect described on p. 96 prevails, resulting in the *anti*-3,5-isomer.

The β -methoxy group in Entry 12 has a similar effect. The aldehydes in Entries 13 and 14 also have α -methyl- β -oxy substitution and the reactions in these cases are with a silyl ketene acetal and silyl thioketene acetal, respectively, resulting in a 3,4-*syn* relationship between the newly formed hydroxyl and α -methyl substituents.

Entry 15 involves a benzyloxy group at C(2) and is consistent with control by a β -oxy substituent, which in this instance is part of a ring. The *anti* relationship between the C(2) and the C(3) groups results from steric control by the branched substituent in the silyl enol ether. The stereogenic center in the ring has only a modest effect.

2.1.5.2. Stereochemical Control by the Enolate or Enolate Equivalent. The facial selectivity of aldol addition reactions can also be controlled by stereogenic centers in the nucleophile. A stereocenter can be located at any of the adjacent positions on an enolate or enolate equivalent. The configuration of the substituent can influence the direction of approach of the aldehyde.

When there is a nonchelating stereocenter at the 1-position of the enolate, the two new stereocenters usually adopt a 2,2'-*syn* relationship to the M substituent. This

result is consistent with a cyclic TS having a conformation of the chiral group with the hydrogen pointed toward the boron and the approach to the aldehyde from the smaller of the other two substituents as in TS **H**.¹⁰⁰

This stereoselectivity, for example, was noted with enolate **2**.¹⁰¹

The same effects are operative with titanium enolates.^{100a}

Little steric differentiation is observed with either the lithium or boron enolates of 2-methyl-2-pentanone.¹⁰²

α -Oxygenated enolates show a strong dependency on the nature of the oxygenated substituent. TBDMS derivatives are highly selective for 2, 2'-*syn*-2,3-*syn* product, but benzyloxy substituents are much less selective. This is attributed to involvement of two competing chelated TSs in the case of benzyloxy, but of a nonchelated TS for the siloxy substituent.¹⁰³ The contrast between the oxy substituents is consistent with the tendency for alkoxy groups to be better donors toward Ti(IV) than siloxy groups.

^{103.} S. Figueras, R. Martin, P. Romea, F. Urpi, and J. Vilarrasa, *Tetrahedron Lett.*, **38**, 1637 (1997).

Oxy substituent	R	2, 2'-syn-2,3-syn:2,2'-anti-2,3-syn
TBDMS	CH ₃	30:1
TBDMS	PhCH ₂	35:1
TBDMS	(CH ₃) ₂ CH	> 95:1
PhCH ₂	CH ₃	5:1
PhCH ₂	PhCH ₂	4:1
PhCH ₂	(CH ₃) ₂ CH	1:1

The stereoselectivity of this reaction also depends on the titanium reagent used to prepare the enolate.¹⁰⁴ When the substituent is benzyloxy, the 2, 2'-*anti*-2,3-syn product is preferred when (*i*-PrO)TiCl₃ is used as the reagent, as would be expected for a chelated TS. However, when TiCl₄ is used, the 2, 2'-*syn*-2,3-syn product is formed. A detailed explanation for this observation has not been established, but it is expected that the benzyloxy derivative would still react through a chelated TS. The reversal on use of TiCl₄ indicates that the identity of the titanium ligands is also an important factor.

High facial selectivity attributable to chelation was observed with the TMS silyl ethers of 3-acyloxy-2-butanone.¹⁰⁵

Several enolates of 4,4-dimethyl-3-(trimethylsiloxy)-2-pentanone have been investigated.¹⁰⁶ The lithium enolate reacts through a chelated TS with high 2,2'-*anti* stereoselectivity, based on the steric differentiation by the *t*-butyl group.

¹⁰⁴. J. G. Solsona, P. Romea, F. Urpi, and J. Villarrasa, *Org. Lett.*, **5**, 519 (2003).

¹⁰⁵. B. M. Trost and H. Urabe, *J. Org. Chem.*, **55**, 3982 (1990).

¹⁰⁶. C. H. Heathcock and S. Arseniyadis, *Tetrahedron Lett.*, **26**, 6009 (1985) and Erratum *Tetrahedron Lett.*, **27**, 770 (1986); N. A. Van Draanen, S. Arseniyadis, M. T. Crimmins, and C. H. Heathcock, *J. Org. Chem.*, **56**, 2499 (1991).

The corresponding di-*n*-butylboron enolate gives the 2,2'-*syn* adduct. The nonchelating boron is thought to react through a TS in which the conformation of the substituent is controlled by a dipolar effect.

The *E*-titanium enolate was prepared by deprotonation with TMP-MgBr, followed by reaction with (*i*-PrO)₃TiCl in the presence of HMPA. The TS for addition is also dominated by a polar effect and gives and 2,2'-*anti* product.

An indication of the relative effectiveness of oxygen substituent in promoting chelation of lithium enolates is found in the enolates **3a–d**. The order of preference for the chelation-controlled product is CH₃OCH₂O > TMSO > PhCH₂O > TBDSO, with the nonchelation product favored for TBDSO.¹⁰⁷

¹⁰⁷. C. Siegel and E. R. Thornton, *Tetrahedron Lett.*, **27**, 457 (1986); A Choudhury and E. R. Thornton, *Tetrahedron Lett.*, **34**, 2221 (1993).

Tin(II) enolates having 3'-benzyloxy substituents are subject to chelation control. The enolate from 2-(benzyloxymethyl)-3-pentanone gave mainly 2,2'-*syn*-2,3-*syn* product, a result that is consistent with a chelated TS.¹⁰⁸

Polar effects appear to be important for 3'-alkoxy substituents in enolates. 3-Benzyloxy groups enhance the facial selectivity of *E*-boron enolates, and this is attributed to a TS **I** in which the benzyloxy group faces toward the approaching aldehyde. This structure is thought to be preferable to an alternate conformation **J**, which may be destabilized by electron pair repulsions between the benzyloxy oxygen and the enolate oxygen.¹⁰⁹

This effect is seen in the case of ketone **4**, where the stereoselectivity of the benzyloxy derivative is much higher than the compound lacking the benzyloxy group.¹¹⁰

The same β -alkoxy effect appears to be operative in a 2'-methoxy substituted system.¹¹¹

¹¹¹. I. Paterson and R. D. Tillyer, *J. Org. Chem.*, **58**, 4182 (1993).

A 3'-benzyloxy ketone gives preferential 2,2'-*syn* stereochemistry through a chelated TS for several titanium enolates. The best results were obtained using isopropoxytitanium trichloride.¹¹² The corresponding *E*-boron enolate gives the 2,2'-*anti*-2,3-*anti* isomer as the main product through a nonchelated TS.¹¹⁰

In summary, the same factors that operate in the electrophile, namely steric, chelation, and polar effects, govern facial selectivity for enolates. The choice of the Lewis acid can determine if the enolate reacts via a chelate. The final outcome depends upon the relative importance of these factors within the particular TS.

Scheme 2.4 provides some specific examples of facial selectivity of enolates. Entry 1 is a case of steric control with Felkin-like TS with approach *anti* to the cyclohexyl group.

Entry 2 is an example of the polar β -oxy directing effect. Entries 3 and 4 involve formation of *E*-enolates using dicyclohexylboron chloride. The stereoselectivity is consistent with a cyclic TS in which a polar effect orients the benzyloxy group away from the enolate oxygen.

Entry 5, where the same stereochemical issues are involved was used in the synthesis of (+)-discodermolide. (See Section 13.5.6 for a more detailed discussion of this synthesis.) There is a suggestion that this entry involves a chelated lithium enolate and there are two stereogenic centers in the aldehyde. In the next section, we discuss how the presence of stereogenic centers in both reactants affects stereoselectivity.

Entry 6 involves a titanium enolate of an ethyl ketone. The aldehyde has no nearby stereocenters. Systems with this substitution pattern have been shown to lead to a 2,2'-*syn* relationship between the methyl groups flanking the ketone, and in this case, the β -siloxy substituent has little effect on the stereoselectivity. The configuration (*Z*) and conformation of the enolate determines the 2,3-*syn* stereochemistry.¹¹³

2.1.5.3. Complementary/Competitive Control: Double Stereodifferentiation. If both the aldehyde and the enolate in an aldol addition are chiral, mutual combinations of stereoselectivity come into play. The chirality in the aldehyde and enolate each impose a bias toward one absolute configuration. The structure of the chairlike TS imposes a bias toward the relative configuration (*syn* or *anti*) of the newly formed stereocenters as described in Section 2.1.2. One combination of configurations, e.g., (*R*)-aldehyde/(*S*)-enolate, provides complementary, reinforcing stereoselection, whereas the alternative combination results in opposing preferences and leads to diminished overall stereoselectivity. The combined interaction of stereocenters in both the aldehyde and the enolate component is called *double stereodifferentiation*.¹¹⁴ The reinforcing combination is called *matched* and the opposing combination is called *mismatched*.

¹¹³ D. A. Evans, D. L. Rieger, M. T. Bilodeau, and F. Urpi, *J. Am. Chem. Soc.*, **113**, 1047 (1991).

¹¹⁴ S. Masamune, W. Choy, J. S. Petersen, and L. R. Sita, *Angew. Chem. Int. Ed. Engl.*, **24**, 1 (1985).

For example the aldol addition of (*S*)-2-cyclohexylpropanal is more stereoselective with the enolate (*S*)-**5** than with the enantiomer (*R*)-**5**. The stereoselectivity of these cases derives from relative steric interactions in the matched and mismatched cases.

Ref. 115

Chelation can also be involved in double stereodifferentiation. The lithium enolate of the ketone **7** reacts selectively with the chiral aldehyde **6** to give a single stereoisomer.¹¹⁶ The enolate is thought to be chelated, blocking one face and leading to the observed product.

There can be more than two stereocenters, in which case there are additional combinations. For example with three stereocenters, there will be one fully matched set, one fully mismatched set, and two partially matched sets. In the latter two, one of the factors may dominate the others. For example, the ketone **8** and the four stereoisomers of the aldehyde **9** have been examined.¹¹⁷ Both the *E*-boron and the *Z*-titanium enolates were studied. The results are shown below.

The results for the boron enolates show that when the aldehyde and enolate centers are matched the diastereoselectivity is high (Cases **A** and **B**). In Case **C**, the enolate is matched with respect to the β -alkoxy group but mismatched with the α -methyl group. The result is an 81:19 dominance of the *anti*-Felkin product. For the titanium enolates, Cases **E** and **F** correspond to a matched relationship with the α -stereocenter. Case **G** is fully mismatched and shows little selectivity. In Case **H**, the matched relationship between the enolate and the β -alkoxy group overrides the α -methyl effect and a 2,3-*syn* (Felkin) product is formed. The corresponding selectivity ratios have also been determined for the lithium enolates.¹¹⁸ Comparison with the boron enolates shows that although the stereoselectivity of the fully matched system is higher with the boron enolate, in the mismatched cases for the lithium enolate, the aldehyde bias overrides the enolate bias and gives modest selectivity for the alternative *anti* isomer.

In general, BF_3 -catalyzed Mukaiyama reactions lack a cyclic organization because of the maximum coordination of four for boron. In these circumstances, the reactions show a preference for the Felkin type of approach and exhibit a preference for *syn* stereoselectivity that is independent of silyl enol ether structure.¹¹⁹

¹¹⁸ D. A. Evans, M. G. Yang, M. J. Dart, and J. L. Duffy, *Tetrahedron Lett.*, **37**, 1957 (1996).

¹¹⁹ D. A. Evans, M. G. Yang, M. J. Dart, J. L. Duffy, and A. S. Kim, *J. Am. Chem. Soc.*, **117**, 9598 (1995).

When there is also a stereogenic center in the silyl enol ether, it can enhance or detract from the underlying stereochemical preferences. The two reactions shown below possess reinforcing structures with regard to the aldehyde α -methyl and the enolate TBDMSO groups and lead to high stereoselectivity. The stereochemistry of the β -TBDMSO group in the aldehyde has little effect on the stereoselectivity.

Scheme 2.5 gives some additional examples of double stereodifferentiation. Entry 1 combines the steric (Felkin) facial selectivity of the aldehyde with the facial selectivity of the enolate, which is derived from chelation. In reaction with the racemic aldehyde, the (*R*)-enantiomer is preferred.

Entry 2 involves the use of a sterically biased enol boronate with an α -substituted aldehyde. The reaction, which gives 40:1 facial selectivity, was used in the synthesis of 6-deoxyerythronolide B and was one of the early demonstrations of the power of double diastereoselection in synthesis. In Entry 3, the *syn* selectivity is the result of a chelated TS, in which the β -*p*-methoxybenzyl substituent interacts with the tin ion.¹²⁰

The aldehyde α -methyl substituent determines the facial selectivity with respect to the aldehyde.

Entry 4 has siloxy substituents in both the (titanium) enolate and the aldehyde. The TBDPSO group in the aldehyde is in the “large” Felkin position, that is, perpendicular to the carbonyl group.¹²¹ The TBDMS group in the enolate is nonchelated but exerts a steric effect that governs facial selectivity.¹²² In this particular case, the two effects are matched and a single stereoisomer is observed.

Entry 5 is a case in which the α - and β -substituents reinforce the stereoselectivity, as shown below. The largest substituent is perpendicular to the carbonyl, as in the Felkin model. When this conformation is incorporated into the TS, with the α -methyl

¹²¹. C. Esteve, M. Ferrero, P. Romea, F. Urpi, and J. Vilarrasa, *Tetrahedron Lett.*, **40**, 5079 (1999).

¹²². S. Figueras, R. Martin, P. Romea, F. Urpi, and J. Vilarrasa, *Tetrahedron Lett.*, **38**, 1637 (1997).

group in the “medium position,” the predicted approach leads to the observed 3,4-*syn* stereochemistry.

Entry 6 is an example of the methodology incorporated into a synthesis of 6-deoxyerythronide.¹²³ Entries 7 and 8 illustrates the operation of the β -alkoxy group in cyclic structures. The reaction in Entry 7 was used in the synthesis of phorbaxazole B.

2.1.5.4. Stereochemical Control Through Chiral Auxiliaries. Another approach to control of stereochemistry is installation of a *chiral auxiliary*, which can achieve a high degree of facial selectivity.¹²⁴ A very useful method for enantioselective aldol reactions is based on the oxazolidinones **10**, **11**, and **12**. These compounds are available in enantiomerically pure form and can be used to obtain either enantiomer of the desired product.

These oxazolidinones can be acylated and converted to the lithium, boron, tin, or titanium enolates by the same methods applicable to ketones and esters. For example, when they are converted to boron enolates using di-*n*-butylboron triflate and triethylamine, the enolates are the *Z*-stereoisomers.¹²⁵

The substituents direct the approach of the aldehyde. The acyl oxazolidinones can be solvolized in water or alcohols to give the enantiomeric β -hydroxy acid or ester. Alternatively, they can be reduced to aldehydes or alcohols.

The reacting aldehyde displaces the oxazolidinone oxygen at the tetravalent boron in the reactive TS. The conformation of the addition TS for boron enolates is believed to have the oxazolidinone ring oriented with opposed dipoles of the ring and the aldehyde carbonyl groups.

The chiral auxiliary methodology using boron enolates has been successfully applied to many complex structures (see also Scheme 2.6).

Titanium enolates also can be prepared from *N*-acyloxazolidinones. These *Z*-enolates, which are chelated with the oxazolidinone carbonyl oxygen,¹²⁸ show *syn* stereoselectivity, and the oxazolidinone substituent exerts facial selectivity.

The *N*-acyloxazolidinones give *anti* products when addition is effected by a catalytic amount of MgCl_2 in the presence of a tertiary amine and trimethylsilyl chloride. Under these conditions the adduct is formed as the trimethylsilyl ether.¹²⁹

Under similar conditions, the corresponding thiazolidinethione derivatives give *anti* product of the *opposite absolute configuration*, at least for cinnamaldehyde.

The mechanistic basis for the stereoselectivity of these conditions remains to be determined. The choice of reactant and conditions can be used to exert a substantial degree of control of the stereoselectivity.

Recently several other molecules have been developed as chiral auxiliaries. These include derivatives of ephedrine and pseudoephedrine. The *N*-methylephedrine [(1*R*,2*S*)-2-dimethylamino-1-phenyl-1-propanol] chiral auxiliary **13** has been examined with both the (*S*)- and (*R*)-enantiomers of 2-benzyloxy-2-methylpropanal.¹³⁰ The two enantiomers reacted quite differently. The (*R*)-enantiomer gave a 60% yield of a pure enantiomer with a *syn* configuration at the new bond. The (*S*)-enantiomer gave a combined 22% yield of two diastereomeric products in a 1.3:1 ratio. The aldehyde is known from NMR studies to form a chelated complex with TiCl_4 ,¹³¹ and presumably reacts through a chelated TS. The TS **J** from the (*R*)-enantiomer has the methyl groups from both the chiral auxiliary and the silyl enol ether in favorable environments (matched pair). The products from the (*S*)-enantiomer arise from TS **K** and

TS **L**, each of which has one of the methyl groups in an unfavorable environment. (mismatched pairs).

Enantioselectivity can also be induced by use of chiral boron enolates. Both the (+) and (−) enantiomers of diisopinocampheylboron triflate have been used to generate *syn* addition through a cyclic TS.¹³² The enantioselectivity was greater than 80% for most cases that were examined. *Z*-Boron enolates are formed under these conditions and the products are 2,3-*syn*.

¹³² I. Paterson, J. M. Goodman, M. A. Lister, R. C. Schumann, C. K. McClure, and R. D. Norcross, *Tetrahedron*, **46**, 4663 (1990).

Another promising boron enolate is derived from (–)-menthone.¹³³ It yields *E*-boron enolates that give good enantioselectivity in the formation of *anti* products.¹³⁴

The boron enolates of α -substituted thiol esters also give excellent facial selectivity.¹³⁵

The facial selectivity in these chiral boron enolates has its origin in the steric effects of the boron substituents.

Several chiral heterocyclic borylating agents have been found useful for enantioselective aldol additions. The diazaborolidine **14** is an example.¹³⁶

Derivatives with various substituted sulfonamides have been developed and used to form enolates from esters and thioesters.¹³⁷ An additional feature of this chiral auxiliary is the ability to select for *syn* or *anti* products, depending upon choice of reagents and reaction conditions. The reactions proceed through an acyclic TS, and diastereoselectivity is determined by whether the *E*- or *Z*-enolate is formed.¹³⁸ *t*-Butyl esters give *E*-enolates and *anti* adducts, whereas phenylthiol esters give *syn* adducts.¹³⁶

Scheme 2.6 shows some examples of the use of chiral auxiliaries in the aldol and Mukaiyama reactions. The reaction in Entry 1 involves an achiral aldehyde and the chiral auxiliary is the only influence on the reaction diastereoselectivity, which is very high. The *Z*-boron enolate results in *syn* diastereoselectivity. Entry 2 has both an α -methyl and a β -benzyloxy substituent in the aldehyde reactant. The 2,3-*syn* relationship arises from the *Z*-configuration of the enolate, and the 3,4-*anti* stereochemistry is determined by the stereocenters in the aldehyde. The product was isolated as an ester after methanolysis. Entry 3, which is very similar to Entry 2, was done on a 60-kg scale in a process development investigation for the potential antitumor agent (+)-discodermolide (see page 1244).

Entries 4 and 5 are cases in which the oxazolidinone substituent is a β -ketoacyl group. The α -hydrogen (between the carbonyls) does not react as rapidly as the γ -hydrogen, evidently owing to steric restrictions to optimal alignment. The all-*syn* stereochemistry is consistent with a TS in which the exocyclic carbonyl is chelated to titanium.

In Entry 5, the aldehyde is also chiral and double stereodifferentiation comes into play. Entry 6 illustrates the use of an oxazolidinone auxiliary with another highly substituted aldehyde. Entry 7 employs conditions that were found effective for α -alkoxyacyl oxazolidinones. Entries 8 and 9 are examples of the application of the thiazolidine-2-thione auxiliary and provide the 2,3-*syn* isomers with diastereofacial control by the chiral auxiliary.

2.1.5.5. Stereochemical Control Through Reaction Conditions. In the early 1990s it was found that the stereochemistry of reactions of boron enolates of *N*-acyloxazolidinones can be altered by using a Lewis acid complex of the aldehyde or an excess of the Lewis acid. These reactions are considered to take place through an open TS, with the stereoselectivity dependent on the steric demands of the Lewis acid. With various aldehydes, TiCl_4 gave a *syn* isomer, whereas the reaction was

anti selective using $(\text{C}_2\text{H}_5)_2\text{AlCl}$.¹³⁹ The *anti* selectivity is proposed to arise as a result of the greater size requirement for the complexed aldehyde with $(\text{C}_2\text{H}_5)_2\text{AlCl}$. These reactions both give a different stereoisomer than the reaction done *without the additional Lewis acid*. The chiral auxiliary is the source of facial selectivity.

With titanium enolates it was found that use of excess (3 equiv.) of the titanium reagent reversed facial selectivity of oxazolidinone enolates.¹⁴⁰ This was attributed to generation of a chelated TS in the presence of the excess Lewis acid. The chelation rotates the oxazolidinone ring and reverses the facial preference, while retaining the *Z*-configuration *syn* diastereoselectivity.

¹³⁹. M. A. Walker and C. H. Heathcock, *J. Org. Chem.*, **56**, 5747 (1991).

¹⁴⁰. M. Nerz-Stormes and E. R. Thornton, *Tetrahedron Lett.*, **27**, 897 (1986); M. Nerz-Stormes and E. R. Thornton, *J. Org. Chem.*, **56**, 2489 (1991).

Crimmins and co-workers have developed *N*-acyloxazolidinethiones as chiral auxiliaries. These reagents show excellent 2,3-*syn* diastereoselectivity and enantioselectivity in additions to aldehydes. The titanium enolates are prepared using TiCl_4 , with (–)-sparteine being a particularly effective base.¹⁴¹

The facial selectivity of these compounds is also dependent on the amount of TiCl_4 that is used. With two equivalents, the facial selectivity is reversed. This reversal is also achieved by adding AgSbF_6 . It was suggested that the excess reagent or the silver salt removes a Cl^- from the titanium coordination sphere and promotes chelation with the thione sulfur.¹⁴² This changes the facial selectivity of the enolate by causing a reorientation of the oxazolidinethione ring. The greater affinity of titanium for sulfur over oxygen makes the oxazolidinethiones particularly effective in these circumstances. The increased tendency for chelation has been observed with other chiral auxiliaries having thione groups.¹⁴³

A related effect is noted with α -alkoxyacyl derivatives. These compounds give mainly the *anti* adducts when a second equivalent of TiCl_4 is added prior to the aldehyde.¹⁴⁴ The *anti* addition is believed to occur through a TS in which the alkoxy oxygen is chelated. In the absence of excess TiCl_4 , a nonchelated cyclic TS accounts for the observed *syn* selectivity.

Camphor-derived sulfonamide can also permit control of enantioselectivity by use of additional Lewis acid. These chiral auxiliaries can be used under conditions in which either cyclic or noncyclic TSs are involved. This frequently allows control of the *syn* or *anti* stereoselectivity.¹⁴³ The boron enolates give *syn* products, but inclusion of SnCl_4 or TiCl_4 gave excellent selectivity for *anti* products and high enantioselectivity for a range of aldehydes.¹⁴⁵

In the case of boron enolates of the camphor sulfonamides, the TiCl_4 -mediated reaction is believed to proceed through an open TS, whereas in its absence, the reaction proceeds through a cyclic TS.

Scheme 2.7 gives some examples of the control of stereoselectivity by use of additional Lewis acid and related methods. Entry 1 shows the effect of the use of excess TiCl_4 . Entry 2 demonstrates the ability of $(\text{C}_2\text{H}_5)_2\text{AlCl}$ to shift the boron enolate toward formation of the 2,3-*anti* diastereomer. Entries 3 and 4 compare the use of one versus two equivalents of TiCl_4 with an oxazolidine-2-thione auxiliary. There is a nearly complete shift of facial selectivity. Entry 5 shows a subsequent application of this methodology. Entries 6 and 7 show the effect of complexation of the aldehyde

with TiCl_4 using the camphor sultam auxiliary. Entry 8 is an example of the use of excess diethylboron triflate to obtain the *anti* stereoisomer in a step in the synthesis of epothilone.

These examples and those in Scheme 2.6 illustrate the key variables that determine the stereochemical outcome of aldol addition reactions using chiral auxiliaries. The first element that has to be taken into account is the configuration of the ring system that is used to establish steric differentiation. Then the nature of the TS, whether it is acyclic, cyclic, or chelated must be considered. Generally for boron enolates, reaction proceeds through a cyclic but nonchelated TS. With boron enolates, excess Lewis acid can favor an acyclic TS by coordination with the carbonyl electrophile. Titanium enolates appear to be somewhat variable but can be shifted to chelated TSs by use of excess reagent and by auxiliaries such as oxazolidine-2-thiones that enhance the tendency to chelation. Ultimately, all of the factors play a role in determining which TS is favored.

2.1.5.6. Enantioselective Catalysis of the Aldol Addition Reaction. There are also several catalysts that can effect enantioselective aldol addition. The reactions generally involve enolate equivalents, such as silyl enol ethers, that are unreactive toward the carbonyl component alone, but can react when activated by a Lewis acid. The tryptophan-based oxazaborolidinone **15** has proven to be a useful catalyst.¹⁴⁸

This catalyst induces preferential *re* facial attack on simple aldehydes, as indicated in Figure 2.2. The enantioselectivity appears to involve the shielding of the *si* face by the indole ring through a π -stacking interaction.

The *B*-3,5-*bis*-(trifluoromethyl)phenyl derivative was found to be a very effective catalyst.¹⁴⁹

¹⁴⁹. K. Ishihara, S. Kondo, and H. Yamamoto, *J. Org. Chem.*, **65**, 9125 (2000).

Fig. 2.2. Origin of facial selectivity in indolylmethyloxazaborolidinone structure. Reproduced from *Tetrahedron: Asymmetry*, **9**, 357 (1998), by permission of Elsevier. (See also color insert.)

An oxazaborolidinone derived from valine is also an effective catalyst. In one case, the two enantiomeric catalysts were completely enantioselective for the newly formed center.¹⁵⁰

Another group of catalysts consist of cyclic borinates derived from tartaric acid. These compounds give good reactivity and enantioselectivity in Mukaiyama aldol reactions. Several structural variations such as **16** and **17** have been explored.¹⁵¹

¹⁵⁰. S. Kiyooka, K. A. Shahid, F. Goto, M. Okazaki, and Y. Shuto, *J. Org. Chem.*, **68**, 7967 (2003).

¹⁵¹. K. Ishihara, T. Maruyama, M. Mouri, Q. Gao, K. Furuta, and H. Yamamoto, *Bull. Chem. Soc. Jpn.*, **66**, 3483 (1993).

These catalysts are believed to function through an acyclic TS. In addition to the normal steric effects of the open TS, the facial selectivity is probably influenced by π stacking with the aryl ring and possibly hydrogen bonding by the formyl hydrogen.¹⁵²

An interesting example of the use of this type of catalysis is a case in which the addition reaction of 3-methylcyclohex-2-en-1-one to 5-methyl-2-hexenal was explored over a range of conditions. The reaction was investigated using both the lithium enolate and the trimethylsilyl enol ether. The yield and stereoselectivity are given for several sets of conditions.¹⁵³ Whereas the lithium enolate and achiral Lewis acids TiCl_4 and BF_3 gave moderate *anti* diastereoselectivity, the catalyst **17** induces good *syn* selectivity, as well as high enantioselectivity.

X	Conditions	Yield	<i>syn</i>	<i>anti</i>	e.e.
Li	(kinetic)	63	18	82	—
Li	(thermo)	66	55	45	—
TMS	TiCl_4	53	15	85	—
TMS	BF_3	68	25	75	—
TMS	Cat 16	51	42	58	24(<i>R</i>)
TMS	Cat 17	94	91	9	99(<i>R</i>)

The lesson from this case is that reactions that are quite unselective under simple Lewis acid catalysis can become very selective with chiral catalysts. Moreover, as this particular case also shows, they can be very dependent on the specific structure of the catalyst.

¹⁵³. K. Takao, T. Tsujita, M. Hara, and K. Tadano, *J. Org. Chem.*, **67**, 6690 (2002).

Another effective group of catalysts is composed of copper *bis*-oxazolines.¹⁵⁴ The chirality is derived from the 4-substituents on the ring.

This and similar catalysts are effective with silyl ketene acetals and silyl thioketene acetals.¹⁵⁵ One of the examples is the tridentate pyridine-BOX-type catalyst **18**. The reactivity of this catalyst has been explored using α - and β -oxy substituted aldehydes.¹⁵⁴ α -Benzyloxyacetaldehyde was highly enantioselective and the α -trimethylsilyloxy derivative was weakly so (56% e.e.). Nonchelating aldehydes such as benzaldehyde and 3-phenylpropanal gave racemic product. 3-Benzyloxypropanal also gave racemic product, indicating that the β -oxy aldehydes do not chelate with this catalyst.

The Cu-BOX catalysts function as Lewis acids at the carbonyl oxygen. The chiral ligands promote facial selectivity, as shown in Figure 2.3.

Several catalysts based on Ti(IV) and BINOL have shown excellent enantioselectivity in Mukaiyama aldol reactions.¹⁵⁶ A catalyst prepared from a 1:1 mixture of BINOL and $\text{Ti}(\text{O}-i\text{-Pr})_4$ gives good results with silyl thioketene acetals in ether, but is very solvent sensitive.¹⁵⁷

The structure of the active catalyst and the mechanism of catalysis have not been completely defined. Several solid state complexes of BINOL and $\text{Ti}(\text{O}-i\text{-Pr})_4$ have been characterized by X-ray crystallography.¹⁵⁸ Figure 2.4 shows the structures of complexes having the composition (BINOLate) $\text{Ti}_2(\text{O}-i\text{-Pr})_6$ and (BINOLate) $\text{Ti}_3(\text{O}-i\text{-Pr})_{10}$.

A titanium catalyst **20** that incorporates binaphthyl chirality along with imine and phenolic (salen) donors is highly active in addition of silyl ketene acetals to aldehydes.¹⁶⁰

This catalyst is also active toward the simple enol ether 2-methoxypropene.¹⁶¹

Entry 6 in Scheme 2.9 is an example of the use of this catalyst in a multistep synthesis.

The enantioselectivity of Sn(II) enolate reactions can be controlled by chiral diamine additives. These reagents are particularly effective for silyl thioketene acetals.¹⁶² Several diamines derived from proline have been explored and 1-methyl-2-(1-piperidinomethyl)pyrrolidine **21** is an example. Even higher enantioselectivity can be achieved by attachment of bicyclic amines to the pyrrolidinomethyl group.¹⁶³

These reactions have been applied to α -benzyloxy and α -(*t*-butyldimethylsiloxy)-thioacetate esters.¹⁶⁴ The benzyloxy derivatives are *anti* selective, whereas the siloxy derivatives are *syn* selective. These differences are attributed to a chelated structure in the case of the benzyloxy derivative and an open TS for the siloxy system.

White and Deerberg explored this reaction system in connection with the synthesis of a portion of the structure of rapamycin.¹⁶⁵ Better yields were observed from benzyloxy than for a methoxy substituent, and there was a slight enhancement of stereoselectivity with the addition of ERG substituents to the benzyloxy group.

Scheme 2.8 gives some examples of chiral Lewis acids that have been used to catalyze aldol and Mukaiyama reactions.

Scheme 2.9 gives some examples of use of enantioselective catalysts. Entries 1 to 4 are cases of the use of the oxazaborolidinone-type of catalyst with silyl enol ethers and silyl ketene acetals. Entries 5 and 6 are examples of the use of BINOL-titanium catalysts, and Entry 7 illustrates the use of Sn(OTf)₂ in conjunction with a chiral amine ligand. The enantioselectivity in each of these cases is determined entirely by the catalyst because there are no stereocenters adjacent to the reaction sites in the reactants.

A different type of catalysis is observed using proline as a catalyst.¹⁶⁶ Proline promotes addition of acetone to aromatic aldehydes with 65–77% enantioselectivity. It has been suggested that the carboxylic acid functions as an intramolecular proton donor and promotes reaction through an enamine intermediate.

2.1.5.7. Summary of Facial Stereoselectivity in Aldol and Mukaiyama Reactions. The examples provided in this section show that there are several approaches to controlling the facial selectivity of aldol additions and related reactions. The *E*- or *Z*-configuration of the enolate and the open, cyclic, or chelated nature of the TS are the departure points for prediction and analysis of stereoselectivity. The Lewis acid catalyst and the donor strength of potentially chelating ligands affect the structure of the TS. Whereas dialkyl boron enolates and BF_3 complexes are tetracoordinate, titanium and tin can be

hexacoordinate. If the reactants are chiral, facial selectivity must be taken into account. Examples of steric, chelation, and polar effects on TS structure have been described. Chiral auxiliaries can influence facial selectivity not only by their inherent steric effects, but also on the basis of the conformation of their Lewis acid complexes. This can be controlled by the choice of the enolate metal and reaction conditions. Dialkylboron enolates react through a cyclic TS that cannot accommodate additional coordination. Titanium and tin enolates of oxazolidinones are chelated under normal conditions, but the use of excess Lewis acid can modify the TS structure and reverse facial selectivity. Chiral catalysts require that additional stereochemical features be taken into account, and the issue becomes the fit of the reactants within the chiral environment. Although most catalysts rely primarily on steric factors for facial selectivity, hydrogen bonding and π stacking can also come into play.

2.1.6. Intramolecular Aldol Reactions and the Robinson Annulation

The aldol reaction can be applied to dicarbonyl compounds in which the two groups are favorably disposed for intramolecular reaction. Kinetic studies on cyclization of 5-oxohexanal, 2,5-hexanedione, and 2,6-heptanedione indicate that formation of five-membered rings is thermodynamically somewhat more favorable than formation of six-membered rings, but that the latter is several thousand times faster.¹⁷⁰ A catalytic amount of acid or base is frequently satisfactory for formation of five- and six-membered rings, but with more complex structures, the techniques required for directed aldol condensations are used.

Scheme 2.10 illustrates intramolecular aldol condensations. Entries 1 and 2 are cases of formation of five-membered rings, with aldehyde groups serving as the electrophilic center. The regioselectivity in Entry 1 is due to the potential for dehydration of only one of the cyclic aldol adducts.

In Entry 2, the more reactive aldehyde group serves as the electrophilic component in preference to the ketone. Entries 3 to 6 are examples of construction of new rings in preexisting cyclic systems. The structure and stereochemistry of the products of these reactions are dictated by ring geometry and the proximity of reactive groups. Entry 5 is interesting in that it results in the formation of a bridgehead double bond. Entries 7 to 9 are intramolecular Mukaiyama reactions, using acetals as the precursor of the electrophilic center. Entry 9, which is a key step in the synthesis of jatrophones, involves formation of an eleven-membered ring. From a retrosynthetic perspective, bonds between a carbinol (or equivalent) carbon and a carbon that is α to a carbonyl carbon are candidates for formation by intramolecular aldol additions.

A particularly important example of the intramolecular aldol reaction is the *Robinson annulation*, a procedure that constructs a new six-membered ring from a ketone.¹⁷¹ The reaction sequence starts with conjugate addition of the enolate to methyl

vinyl ketone or a similar enone. This is followed by cyclization by an intramolecular aldol addition. Dehydration usually occurs to give a cyclohexenone derivative.

Other α,β -unsaturated enones can be used, but the reaction is somewhat sensitive to substitution at the β -carbon and adjustment of the reaction conditions is necessary.¹⁷²

Scheme 2.11 shows some examples of Robinson annulation reactions. Entries 1 and 2 show annulation reactions of relatively acidic dicarbonyl compounds. Entry 3 is an example of use of 4-(trimethylammonio)-2-butanone as a precursor of methyl vinyl ketone. This compound generates methyl vinyl ketone in situ by β -elimination. The original conditions developed for the Robinson annulation reaction are such that the ketone enolate composition is under thermodynamic control. This usually results in the formation of product from the more stable enolate, as in Entry 3. The C(1) enolate is preferred because of the conjugation with the aromatic ring. For monosubstituted cyclohexanones, the cyclization usually occurs at the more-substituted position in hydroxylic solvents. The alternative regiochemistry can be achieved by using an enamine. Entry 4 is an example. As discussed in Section 1.9, the less-substituted enamine is favored, so addition occurs at the less-substituted position.

Conditions for kinetic control of enolate formation can be applied to the Robinson annulation to control the regiochemistry of the reaction. Entries 5 and 6 of Scheme 2.11 are cases in which the reaction is carried out on a preformed enolate. Kinetic

control is facilitated by use of somewhat more activated enones, such as methyl 1-(trimethylsilyl)vinyl ketone.

Ref. 173

The role of the trimethylsilyl group is to stabilize the enolate formed in the conjugate addition. The silyl group is then removed during the dehydration step. Methyl 1-trimethylsilylvinyl ketone can be used under aprotic conditions that are compatible with regiospecific methods for enolate generation. The direction of annulation of unsymmetrical ketones can therefore be controlled by the method of enolate formation.

Ref. 174

Methyl 1-phenylthiovinyl ketones can also be used as enones in kinetically controlled Robinson annulation reactions, as illustrated by Entry 6. Entry 7 shows an annulation using silyl enol ether as the enolate equivalent. These reactions are called *Mukaiyama-Michael reactions* (see Section 2.6.3).

The Robinson annulation is a valuable method for preparing bicyclic and tricyclic structures that can serve as starting materials for the preparation of steroids and terpenes.¹⁷⁵ Reaction with 2-methylcyclohexan-1,3-dione gives a compound called the *Wieland-Miescher ketone*.

A similar reaction occurs with 2-methylcyclopentane-1,3-dione,¹⁷⁶ and can be done enantioselectively by using the amino acid L-proline to form an enamine intermediate. The (*S*)-enantiomer of the product is obtained in high enantiomeric excess.¹⁷⁷

The detailed mechanism of this enantioselective transformation remains under investigation.¹⁷⁸ It is known that the acidic carboxylic group is crucial, and the cyclization is believed to occur via the enamine derived from the catalyst and the exocyclic ketone. A computational study suggested that the proton transfer occurs through a TS very similar to that described for the proline-catalyzed aldol reaction (see page 132).¹⁷⁹

Visual models, additional information and exercises on Proline-Catalyzed Aldol Reactions can be found in the Digital Resource available at: Springer.com/carey-sundberg.

2.2. Addition Reactions of Imines and Iminium Ions

Imines and iminium ions are nitrogen analogs of carbonyl compounds and they undergo nucleophilic additions like those involved in aldol reactions. The reactivity order is $C=NR < C=O < [C=NR_2]^+ < [C=OH]^+$. Because iminium ions are more reactive than imines, the reactions are frequently run under mildly acidic conditions. Under some circumstances, the iminium ion can be the reactive species, even though it is a minor constituent in equilibrium with the amine, carbonyl compound, and unprotonated imine.

Addition of enols, enolates, or enolate equivalents to imines or iminium ions provides an important route to β -amino ketones.

2.2.1. The Mannich Reaction

The *Mannich reaction* is the condensation of an enolizable carbonyl compound with an iminium ion.¹⁸⁰ It is usually done using formaldehyde and introduces an α -dialkylaminomethyl substituent.

The electrophile is often generated in situ from the amine and formaldehyde.

The reaction is normally limited to secondary amines, because dialkylation can occur with primary amines. The dialkylation reaction can be used to advantage in ring closures.

Ref. 181

Scheme 2.12 shows some representative Mannich reactions. Entries 1 and 2 show the preparation of typical “Mannich bases” from a ketone, formaldehyde, and a dialkylamine following the classical procedure. Alternatively, formaldehyde equivalents may be used, such as *bis*-(dimethylamino)methane in Entry 3. On treatment with trifluoroacetic acid, this aminal generates the iminium trifluoroacetate as a reactive electrophile. *N,N*-(Dimethyl)methylene ammonium iodide is commercially available and is known as *Eschenmoser’s salt*.¹⁸² This compound is sufficiently electrophilic to react directly with silyl enol ethers in neutral solution.¹⁸³ The reagent can be added to a solution of an enolate or enolate precursor, which permits the reaction to be carried out under nonacidic conditions. Entries 4 and 5 illustrate the preparation of Mannich bases using Eschenmoser’s salt in reactions with preformed enolates.

The dialkylaminomethyl ketones formed in the Mannich reaction are useful synthetic intermediates.¹⁸⁴ Thermal elimination of the amines or the derived quaternary salts provides α -methylene carbonyl compounds.

conjugate addition reactions carried out by in situ generation of α,β -unsaturated carbonyl compounds from Mannich bases.

α -Methylenelactones are present in a number of natural products.¹⁸⁶ The reaction of ester enolates with *N,N*-(dimethyl)methyleneammonium trifluoroacetate,¹⁸⁷ or Eschenmoser's salt,¹⁸⁸ has been used for introduction of the α -methylene group in the synthesis of vernolepin, a compound with antileukemic activity.^{189,190}

Mannich reactions, or a mechanistic analog, are important in the biosynthesis of many nitrogen-containing natural products. As a result, the Mannich reaction has played an important role in the synthesis of such compounds, especially in syntheses patterned after the biosynthesis, i.e., *biomimetic synthesis*. The earliest example of the use of the Mannich reaction in this way was Sir Robert Robinson's successful synthesis of tropinone, a derivative of the alkaloid tropine, in 1917.

Ref. 191

As with aldol and Mukaiyama addition reactions, the Mannich reaction is subject to enantioselective catalysis.¹⁹² A catalyst consisting of Ag^+ and the chiral imino aryl phosphine **22** achieves high levels of enantioselectivity with a range of *N*-(2-methoxyphenyl)imines.¹⁹³ The 2-methoxyphenyl group is evidently involved in an interaction with the catalyst and enhances enantioselectivity relative to other *N*-aryl substituents. The isopropanol serves as a proton source and as the ultimate acceptor of the trimethyl silyl group.

A zinc catalyst **23** was found effective for aryl hydroxymethyl ketones in reactions with glyoxylic imines. In this case, the 4-methoxy-2-methylphenylimines gave the best results.¹⁹⁴ Interestingly, the 2-methoxyphenyl ketone gave substantially enhanced 2,3-diastereoselectivity (20:1) compared to about 10:1 for most other aryl groups, suggesting that the *o*-methoxy group may introduce an additional interaction with the catalyst. All the compounds gave e.e. > 95%.

Other types of catalysts that are active in Mannich reactions include the Cu-bis-oxazolines.¹⁹⁵ Most of the cases examined to date are for relatively reactive imines, such as those derived from glyoxylate or pyruvate esters.

As already discussed for aldol and Robinson annulation reactions, proline is also a catalyst for enantioselective Mannich reactions. Proline effectively catalyzes the reactions of aldehydes such as 3-methylbutanal and hexanal with *N*-arylimines of ethyl glyoxalate.¹⁹⁶ These reactions show 2,3-*syn* selectivity, although the products with small alkyl groups tend to isomerize to the *anti* isomer.

With aromatic aldehydes, d.r. ranged up to more than 10:1 for propanal.

The proline-catalyzed reaction has been extended to the reaction of propanal, butanal, and pentanal with a number of aromatic aldehydes and proceeds with high *syn* selectivity.¹⁹⁷ The reaction can also be carried out under conditions in which the imine is formed in situ. Under these conditions, the conjugative stabilization of the aryl imines leads to the preference for the aryl imine to act as the electrophile. A good yield of the expected β -aminoalcohol was obtained with propanal serving as both the nucleophilic and the electrophilic component. The product was isolated as a γ -amino alcohol after reduction with NaBH_4 .

Ketones such as acetone, hydroxyacetone, and methoxyacetone can be condensed with both aromatic and aliphatic aldehydes.¹⁹⁸

The TS proposed for these proline-catalyzed reactions is very similar to that for the proline-catalyzed aldol addition (see p. 132). In the case of imines, however, the aldehyde substituent is directed *toward* the enamine double bond because of the dominant steric effect of the *N*-aryl substituent. This leads to formation of *syn* isomers, whereas the aldol reaction leads to *anti* isomers. This is the TS found to be the most stable by B3LYP/6-31G* computations.¹⁹⁹ The proton transfer is essentially complete at the TS. As with the aldol addition TS, the enamine is oriented *anti* to the proline carboxy group in the most stable TS.

Structure **24**, which is a simplification of an earlier catalyst,²⁰⁰ gives excellent results with *N*-*t*-butoxycarbonylimines.²⁰¹ Catalysts of this type are thought to function through hydrogen-bonding interactions.

2.2.2. Additions to *N*-Acyl Iminium Ions

Even more reactive C=N bonds are present in *N*-acyliminium ions.²⁰²

Gas phase reactivity toward allyltrimethylsilane was used to compare the reactivity of several cyclic *N*-acyliminium ions and related iminium ions.²⁰³ Compounds with endocyclic acyl groups were found to be more reactive than compounds with exocyclic acyl substituents. Five-membered ring compounds are somewhat more reactive than six-membered ones. The higher reactivity of the endocyclic acyl derivatives is believed to be due to geometric constraints that maximize the polar effect of the carbonyl group.

N-Acyliminium ions are usually prepared in situ in the presence of a potential nucleophile. There are several ways of generating acyliminium ions. Cyclic examples can be generated by partial reduction of imides.²⁰⁴

Various oxidations of amides or carbamates can also generate acyliminium ions. An electrochemical oxidation forms α -alkoxy amides and lactams, which then generate

acyliminium ions.²⁰⁵ *N*-Acyliminium ions can also be obtained by oxidative decarboxylation of *N*-acyl- α -amino acids such as *N*-acyl proline derivatives.²⁰⁶

Acyliminium ions are sufficiently electrophilic to react with enolate equivalents such as silyl enol ethers²⁰⁷ and isopropenyl acetate.²⁰⁸

Acyliminium ions can be used in enantioselective additions with enolates having chiral auxiliaries, such as *N*-acyloxazolidinones or *N*-acylthiazolidinethiones.

Scheme 2.13 gives some examples of Knoevenagel condensation reactions.

2.3. Acylation of Carbon Nucleophiles

The reactions that are discussed in this section involve addition of carbon nucleophiles to carbonyl centers having a potential leaving group. The tetrahedral intermediate formed in the addition step reacts by expulsion of the leaving group. The overall

transformation results in the *acylation* of the carbon nucleophile. This transformation corresponds to the general reaction Path **B**, as specified at the beginning of this chapter (p. 64).

The reaction pattern can be used for the synthesis of 1,3-dicarbonyl compounds and other systems in which an acyl group is β to an anion-stabilizing group.

2.3.1. Claisen and Dieckmann Condensation Reactions

An important group of acylation reactions involves esters, in which case the leaving group is alkoxy or aryloxy. The self-condensation of esters is known as the *Claisen condensation*.²¹⁶ Ethyl acetoacetate, for example, is prepared by Claisen condensation of ethyl acetate. All of the steps in the mechanism are reversible, and a full equivalent of base is needed to bring the reaction to completion. Ethyl acetoacetate is more acidic than any of the other species present and is converted to its conjugate base in the final step. The β -ketoester product is obtained after neutralization.

As a practical matter, the alkoxide used as the base must be the same as the alcohol portion of the ester to prevent product mixtures resulting from ester interchange. Sodium hydride with a small amount of alcohol is frequently used as the base for ester condensation. The reactive base is the sodium alkoxide formed by reaction of sodium hydride with the alcohol released in the condensation.

As the final proton transfer cannot occur when α -substituted esters are used, such compounds do not condense under the normal reaction conditions, but this limitation

²¹⁶ C. R. Hauser and B. E. Hudson, Jr., *Org. React.*, **1**, 266 (1942).

can be overcome by use of a very strong base that converts the reactant ester completely to its enolate. Entry 2 of Scheme 2.14 illustrates the use of triphenylmethylsodium for this purpose. The sodium alkoxide is also the active catalyst in procedures that use sodium metal, such as in Entry 3 in Scheme 2.14. The alkoxide is formed by reaction of the alcohol that is formed as the reaction proceeds.

The intramolecular version of ester condensation is called the *Dieckmann condensation*.²¹⁷ It is an important method for the formation of five- and six-membered rings and has occasionally been used for formation of larger rings. As ester condensation is reversible, product structure is governed by thermodynamic control, and in situations where more than one product can be formed, the product is derived from the most stable enolate. An example of this effect is the cyclization of the diester **25**.²¹⁸ Only **27** is formed, because **26** cannot be converted to a stable enolate. If **26**, synthesized by another method, is subjected to the conditions of the cyclization, it is isomerized to **27** by the reversible condensation mechanism.

Entries 3 to 8 in Scheme 2.14 are examples of Dieckmann condensations. Entry 6 is a Dieckmann reaction carried out under conventional conditions, followed by decarboxylation. The product is a starting material for the synthesis of a number of sarpagine-type indole alkaloids and can be carried out on a 100-g scale. The combination of a Lewis acid, such as MgCl_2 , with an amine can also promote Dieckmann cyclization.²¹⁹ Entry 7, which shows an application of these conditions, is a step in the synthesis of a potential drug. These conditions were chosen to avoid the use of TiCl_4 in a scale-up synthesis and can be done on a 60-kg scale. The 14-membered ring formation in Entry 8 was carried out under high dilution by slowly adding the reactant to the solution of the NaHMDS base. The product is a mixture of both possible regioisomers (both the 5- and 7-carbomethoxy derivatives are formed) but a single product is obtained after decarboxylation.

Mixed condensations of esters are subject to the same general restrictions as outlined for mixed aldol reactions (Section 2.1.2). One reactant must act preferentially as the acceptor and another as the nucleophile for good yields to be obtained. Combinations that work best involve one ester that cannot form an enolate but is relatively reactive as an electrophile. Esters of aromatic acids, formic acid, and oxalic acid are especially useful. Some examples of mixed ester condensations are shown in Section C of Scheme 2.14. Entries 9 and 10 show diethyl oxalate as the acceptor, and aromatic esters function as acceptors in Entries 11 and 12.

2.3.2. Acylation of Enolates and Other Carbon Nucleophiles

Acylation of carbon nucleophiles can also be carried out with more reactive acylating agents such as acid anhydrides and acyl chlorides. These reactions must

be done in nonnucleophilic solvents to avoid solvolysis of the acylating agent. The use of these reactive acylating agents can be complicated by competing O-acylation. Magnesium enolates play a prominent role in these C-acylation reactions. The magnesium enolate of diethyl malonate, for example, can be prepared by reaction with magnesium metal in ethanol. It is soluble in ether and undergoes C-acylation by acid anhydrides and acyl chlorides. The preparation of diethyl benzoylmalonate (Entry 1, Scheme 2.15) is an example of the use of an acid anhydride. Entries 2 to 5 illustrate the use of acyl chlorides. Entry 3 is carried out in basic aqueous solution and results in deacylation of the initial product.

Monoalkyl esters of malonic acid react with Grignard reagents to give a chelated enolate of the malonate monoanion.

These carbon nucleophiles react with acyl chlorides²²⁰ or acyl imidazolides.²²¹ The initial products decarboxylate readily so the isolated products are β -ketoesters.

Acyl imidazolides are more reactive than esters but not as reactive as acyl halides. Entry 7 is an example of formation of a β -ketoesters by reaction of magnesium enolate monoalkyl malonate ester by an imidazolide. Acyl imidazolides also are used for acylation of ester enolates and nitromethane anion, as illustrated by Entries 8, 9, and 10. *N*-Methoxy-*N*-methyamides are also useful for acylation of ester enolates.

Ref. 222

Both diethyl malonate and ethyl acetoacetate can be acylated by acyl chlorides using magnesium chloride and pyridine or triethylamine.²²³

Rather similar conditions can be used to convert ketones to β -keto acids by carboxylation.²²⁴

These reactions presumably involve formation of a magnesium chelate of the keto acid. The β -ketoacid is liberated when the reaction mixture is acidified during workup.

Carboxylation of ketones and esters can also be achieved by using the magnesium salt of monomethyl carbonate.

Ref. 226

The enolates of ketones can be acylated by esters and other acylating agents. The products of these reactions are β-dicarbonyl compounds, which are rather acidic and can be alkylated by the procedures described in Section 1.2. Reaction of ketone enolates with formate esters gives a β-ketoaldehyde. As these compounds exist in the enol form, they are referred to as *hydroxymethylene derivatives*. Entries 1 and 2 in Scheme 2.16 are examples. Product formation is under thermodynamic control so the structure of the product can be predicted on the basis of the stability of the various possible product anions.

Ketones are converted to β-ketoesters by acylation with diethyl carbonate or diethyl oxalate, as illustrated by Entries 4 and 5 in Scheme 2.16. Alkyl cyanofornate can be used as the acylating reagent under conditions where a ketone enolate has been formed under kinetic control.²²⁷

When this type of reaction is quenched with trimethylsilyl chloride, rather than by neutralization, a trimethylsilyl ether of the adduct is isolated. This result shows that the tetrahedral adduct is stable until the reaction mixture is hydrolyzed.

Ref. 228

β-Keto sulfoxides can be prepared by acylation of dimethyl sulfoxide anion with esters.²²⁹

Ref. 231

These reactions accomplish the same overall synthetic transformation as the acylation of ester enolates, but use desulfurization rather than decarboxylation to remove the anion-stabilizing group. Dimethyl sulfone can be subjected to similar reaction sequences.²³²

2.4. Olefination Reactions of Stabilized Carbon Nucleophiles

This section deals with reactions that correspond to Pathway C, defined earlier (p. 64), that lead to formation of alkenes. The reactions discussed include those of phosphorus-stabilized nucleophiles (Wittig and related reactions), a α -silyl (Peterson reaction) and α -sulfonyl (Julia olefination) with aldehydes and ketones. These important reactions can be used to convert a carbonyl group to an alkene by reaction with a carbon nucleophile. In each case, the addition step is followed by an elimination.

A crucial issue for these reactions is the stereoselectivity for formation of *E*- or *Z*-alkene. This is determined by the mechanisms of the reactions and, as we will see, can be controlled in some cases by the choice of particular reagents and reaction conditions.

2.4.1. The Wittig and Related Reactions of Phosphorus-Stabilized Carbon Nucleophiles

The *Wittig reaction* involves *phosphonium ylides* as the nucleophilic carbon species.²³³ An ylide is a molecule that has a contributing resonance structure with opposite charges on adjacent atoms, each of which has an octet of electrons. Although this definition includes other classes of compounds, the discussion here is limited to ylides having the negative charge on the carbon. Phosphonium ylides are stable, but quite reactive, compounds. They can be represented by two limiting resonance structures, which are referred to as the ylide and ylene forms.

NMR spectroscopic studies (^1H , ^{13}C , and ^{31}P) are consistent with the dipolar ylide structure and suggest only a minor contribution from the ylene structure.²³⁴ Theoretical calculations support this view.²³⁵ The phosphonium ylides react with carbonyl compounds to give olefins and the phosphine oxide.

There are related reactions involving phosphonate esters or phosphines oxides. These reactions differ from the Wittig reaction in that they involve *anions* formed by deprotonation. In the case of the phosphonate esters, a second EWG substituent is usually present.

2.4.1.1. Olefination Reactions Involving Phosphonium Ylides. The synthetic potential of phosphonium ylides was developed initially by G. Wittig and his associates at the University of Heidelberg. The reaction of a phosphonium ylide with an aldehyde or ketone introduces a carbon-carbon double bond in place of the carbonyl bond. The mechanism originally proposed involves an addition of the nucleophilic ylide carbon to the carbonyl group to form a dipolar intermediate (a *betaine*), followed by elimination of a phosphine oxide. The elimination is presumed to occur after formation of a four-membered *oxaphosphetane* intermediate. An alternative mechanism proposes direct formation of the oxaphosphetane by a cycloaddition reaction.²³⁶ There have been several computational studies that find the oxaphosphetane structure to be an intermediate.²³⁷ Oxaphosphetane intermediates have been observed by NMR studies at low temperature.²³⁸ Betaine intermediates have been observed only under special conditions that retard the cyclization and elimination steps.²³⁹

Phosphonium ylides are usually prepared by deprotonation of phosphonium salts. The phosphonium salts that are used most often are alkyltriphenylphosphonium halides, which can be prepared by the reaction of triphenylphosphine and an alkyl halide. The alkyl halide must be reactive toward S_N2 displacement.

Alkyltriphenylphosphonium halides are only weakly acidic, and a strong base must be used for deprotonation. Possibilities include organolithium reagents, the anion of dimethyl sulfoxide, and amide ion or substituted amide anions, such as LDA or NaHMDS. The ylides are not normally isolated, so the reaction is carried out either with the carbonyl compound present or with it added immediately after ylide formation. Ylides with nonpolar substituents, e.g., $\text{R} = \text{H}$, alkyl, aryl, are quite reactive toward both ketones and aldehydes. Ylides having an α -EWG substituent, such as alkoxycarbonyl or acyl, are less reactive and are called *stabilized ylides*.

The stereoselectivity of the Wittig reaction is believed to be the result of steric effects that develop as the ylide and carbonyl compound approach one another. The three phenyl substituents on phosphorus impose large steric demands that govern the formation of the diastereomeric adducts.²⁴⁰ Reactions of unstabilized phosphoranes are believed to proceed through an early TS, and steric factors usually make these reactions selective for the *cis*-alkene.²⁴¹ Ultimately, however, the precise stereoselectivity is dependent on a number of variables, including reactant structure, the base used for ylide formation, the presence of other ions, solvent, and temperature.²⁴²

Scheme 2.17 gives some examples of Wittig reactions. Entries 1 to 5 are typical examples of using ylides without any functional group stabilization. The stereoselectivity depends strongly on both the structure of the ylide and the reaction conditions. Use of sodium amide or NaHMDS as bases gives higher selectivity for *Z*-alkenes than do ylides prepared with alkyllithium reagents as base (see Entries 3 to 6). Benzyli-denetriphenylphosphorane (Entry 6) gives a mixture of both *cis*- and *trans*-stilbene on reaction with benzaldehyde. The diminished stereoselectivity is attributed to complexes involving the lithium halide salt that are present when alkyllithium reagents are used as bases.

β -Ketophosphonium salts are considerably more acidic than alkylphosphonium salts and can be converted to ylides by relatively weak bases. The resulting ylides, which are stabilized by the carbonyl group, are substantially less reactive than unfunctionalized ylides. More vigorous conditions are required to bring about reactions with ketones. Stabilized ylides such as (carboethoxymethylidene)triphenylphosphorane (Entries 8 and 9) react with aldehydes to give exclusively *trans* double bonds.

When a hindered ketone is to be converted to a methylene derivative, the best results are obtained if potassium *t*-alkoxide is used as the base in a hydrocarbon solvent. Under these conditions the reaction can be carried out at elevated temperatures.²⁴³ Entries 10 and 11 illustrate this procedure.

The reaction of nonstabilized ylides with aldehydes can be induced to yield *E*-alkenes with high stereoselectivity by a procedure known as the *Schlosser modification* of the Wittig reaction.²⁴⁴ In this procedure, the ylide is generated as a lithium halide complex and allowed to react with an aldehyde at low temperature, presumably forming a mixture of diastereomeric betaine-lithium halide complexes. At the temperature at which the addition is carried out, there is no fragmentation to an alkene and triphenylphosphine oxide. This complex is then treated with an equivalent of strong base such as phenyllithium to form a β -oxido ylide. Addition of one equivalent of *t*-butyl alcohol protonates the β -oxido ylide stereoselectivity to give the *syn*-betaine as a lithium halide complex. Warming the solution causes the *syn*-betaine-lithium halide complex to give *trans*-alkene by a *syn* elimination.

An extension of this method can be used to prepare allylic alcohols. Instead of being protonated, the β -oxido ylide is allowed to react with formaldehyde. The β -oxido ylide and formaldehyde react to give, on warming, an allylic alcohol. Entry 12 is an example of this reaction. The reaction is valuable for the stereoselective synthesis of *Z*-allylic alcohols from aldehydes.²⁴⁵

The Wittig reaction can be applied to various functionalized ylides.²⁴⁶ Methoxymethylene and phenoxymethylene ylides lead to vinyl ethers, which can be hydrolyzed to aldehydes.²⁴⁷

Ref. 248

2-(1,3-Dioxolanyl)methyl ylides can be used for the introduction of α,β -unsaturated aldehydes (see Entry 15, Scheme 2.17). Methyl ketones can be prepared by a reaction using the α -methoxyethylidene phosphorane.

Ref. 249

There have been many applications of the Wittig reaction in multistep syntheses. The reaction can be used to prepare extended conjugated systems, such as crocetin dimethyl ester, which has seven conjugated double bonds. In this case, two cycles of Wittig reactions using stabilized ylides provided the seven double bonds. Note the use of a conjugated stabilized ylide in the second step.²⁵⁰

In several cases of syntheses of highly functionalized molecules, use of CH_3Li - LiBr for ylide formation has been found to be advantageous. For example, in the synthesis of milbemycin D, Crimmins and co-workers obtained an 84% yield with 10:1 *Z:E* selectivity.²⁵¹ In this case, the more stable *E*-isomer was required and it was obtained by I_2 -catalyzed isomerization.

This methodology was also used in the connecting of two major fragments in the synthesis of spongistatins.²⁵²

These conditions were also employed for a late stage of the synthesis of (+)-discodermolide (see Entry 17, Scheme 2.17).

2.4.1.2. Olefination Reactions Involving Phosphonate Anions. An important complement to the Wittig reaction involves the reaction of phosphonate carbanions with carbonyl compounds.²⁵³ The alkylphosphonic acid esters are made by the reaction of an alkyl halide, preferably primary, with a phosphite ester. Phosphonate carbanions are generated by treating alkylphosphonate esters with a base such as sodium hydride, *n*-butyllithium, or sodium ethoxide. Alumina coated with KF or KOH has also found use as the base.²⁵⁴

Reactions with phosphonoacetate esters are used frequently to prepare α,β -unsaturated esters. This reaction is known as the *Wadsworth-Emmons reaction* and usually leads to the *E*-isomer.

The conditions can be modified to favor the *Z*-isomer. Use of KHMDS with 18-crown-6 favors the *Z*-product.²⁵⁵ This method was used, for example, to control the

stereochemistry in the synthesis of the *Z*- and *E*-isomers of β -santalol, a fragrance that is a component of sandalwood oil.

Several modified phosphonoacetate esters show selectivity for the *Z*-enoate product. Trifluoroethyl,²⁵⁶ phenyl,²⁵⁷ 2-methylphenyl,²⁵⁸ and 2,6-difluorophenyl²⁵⁹ esters give good *Z*-stereoselectivity with aldehydes. The trifluoroethyl esters also give *Z*-selectivity with ketones.²⁶⁰

Several other methodologies have been developed for control of the stereoselectivity of Wadsworth-Emmons reactions. For example, K_2CO_3 in chlorobenzene with a catalytic amount of 18-crown-6 is reported to give excellent *Z*-selectivity.²⁶¹ Another group found that use of excess Na^+ , added as NaI, improved *Z*-selectivity for 2-methylphenyl esters.

An alternative procedure for effecting the condensation of phosphonoacetates is to carry out the reaction in the presence of lithium chloride and an amine such as diisopropylethylamine. The lithium chelate of the substituted phosphonate is sufficiently acidic to be deprotonated by the amine.²⁶²

This version of the Wadsworth-Emmons reaction has been used in the scaled-up syntheses of drugs and drug-candidate molecules. For example, it is used to prepare a cinnamate ester that is a starting material for pilot plant synthesis of a potential integrin antagonist.²⁶³

Entries 10 and 11 of Scheme 2.18 also illustrate this procedure.

Scheme 2.18 gives some representative olefination reactions of phosphonate anions. Entry 1 represents a typical preparative procedure. Entry 2 involves formation of a 2,4-dienoate ester using an α,β -unsaturated aldehyde. Diethyl benzylphosphonate can be used in the Wadsworth-Emmons reaction, as illustrated by Entry 3. Entries 4 to 6 show other anion-stabilizing groups. Intramolecular reactions can be used to prepare cycloalkenes.²⁶⁴

Ref. 265

Intramolecular condensation of phosphonate carbanions with carbonyl groups carried out under conditions of high dilution have been utilized in macrocycle syntheses. Entries 7 and 8 show macrocyclizations involving the Wadsworth-Emmons reaction. Entries 9 to 11 illustrate the construction of new double bonds in the course of a multistage synthesis. The LiCl/amine conditions are used in Entries 9 and 10.

The stereoselectivity of the reactions of stabilized phosphonate anions is usually considered to be the result of reversible adduct formation, followed by rate/product-controlling elimination that favors the *E*-isomer. This matter has been investigated by computation. The Wadsworth-Emmons reaction between lithio methyl dimethylphosphonoacetate and acetaldehyde has been modeled at the HF/6-31G* level. Energies were also calculated at the B3LYP/6-31G* level.²⁶⁶ The energy profile for the intermediates and TSs are shown in Figure 2.5. In agreement with the prevailing experimental interpretation, the highest barrier is for formation of the oxaphosphetane and the addition step is reversible. The stereochemistry, then, is determined by the relative ease of formation of the stereoisomeric oxaphosphetanes. The oxaphosphetane species is of marginal stability and proceeds rapidly to product. At the B3LYP/6-31 + G* level, TS2_{trans} is 2.2 kcal/mol more stable than TS2_{cis}. The path to the *cis* product encounters two additional small barriers associated with slightly stable stereoisomeric

oxaphosphetane intermediates. The oxaphosphatane is not a stable intermediate on the path to *trans* product.

Visual models, additional information and exercises on the Wadsworth-Emmons Reaction can be found in the Digital Resource available at: Springer.com/carey-sundberg.

Fig. 2.6. Free-energy profile (B3LYP/6-31 + G* with ZPE correction) for intermediates and transition structures for Wadsworth-Emmons reactions between the lithium enolate of trimethyl phosphonoacetate anion and formaldehyde in the gas phase and in tetrahydrofuran or ethanol. Adapted from *J. Org. Chem.*, **63**, 1280 (1998), by permission of the American Chemical Society.

Another computational study included a solvation model.²⁶⁷ Solvation strongly stabilized the oxyanion adduct, suggesting that its formation may be rate and product determining under certain circumstances. When this is true, analysis of stereoselectivity must focus on the addition TS. Figure 2.6 shows the computed energy profile for the TSs and intermediates. TS1 is the structure leading to the oxyanion intermediate. According to the energy profile, its formation is irreversible in solution and therefore determines the product stereochemistry. The structure shows a rather small (30° – 35°) dihedral angle and suggests that steric compression would arise with a *Z*-substituent.

Structure **3** is the intermediate oxyanion adduct. TS2 is the structure leading to cyclization of the oxyanion to the oxaphosphetane. Structure **4a** is the oxaphosphetane, and the computation shows only a small barrier for its conversion to product.

Carbanions derived from phosphine oxides also add to carbonyl compounds. The adducts are stable but undergo elimination to form alkene on heating with a base such as sodium hydride. This reaction is known as the *Horner-Wittig* reaction.²⁶⁸

²⁶⁷ P. Brandt, P.-O. Norrby, I. Martin, and T. Rein, *J. Org. Chem.*, **63**, 1280 (1998).

²⁶⁸ For a review, see J. Clayden and S. Warren, *Angew. Chem. Int. Ed. Engl.*, **35**, 241 (1996).

The unique feature of the Horner-Wittig reaction is that the addition intermediate can be isolated and purified, which provides a means for control of the reaction's stereochemistry. It is possible to separate the two diastereomeric adducts in order to prepare the pure alkenes. The elimination process is *syn*, so the stereochemistry of the alkene that is formed depends on the stereochemistry of the adduct. Usually the *anti* adduct is the major product, so it is the *Z*-alkene that is favored. The *syn* adduct is most easily obtained by reduction of β -ketophosphine oxides.²⁶⁹

2.4.2. Reactions of α -Trimethylsilylcarbanions with Carbonyl Compounds

Trialkylsilyl groups have a modest stabilizing effect on adjacent carbanions (see Part A, Section 3.4.2). Reaction of the carbanions with carbonyl compounds gives β -hydroxyalkylsilanes. β -Hydroxyalkylsilanes are converted to alkenes by either acid or base.²⁷⁰ These eliminations provide the basis for a synthesis of alkenes. The reaction is sometimes called the *Peterson reaction*.²⁷¹ For example, the Grignard reagent derived from chloromethyltrimethylsilane adds to an aldehyde or ketone and the intermediate can be converted to a terminal alkene by acid or base.²⁷²

Alternatively, organolithium reagents of the type $(\text{CH}_3)_3\text{SiCH}(\text{Li})\text{Z}$, where Z is a carbanion-stabilizing substituent, can be prepared by deprotonation of $(\text{CH}_3)_3\text{SiCH}_2\text{Z}$ with *n*-butyllithium.

These reagents usually react with aldehydes and ketones to give substituted alkenes directly. No separate elimination step is necessary because fragmentation of the intermediate occurs spontaneously under the reaction conditions.

In general, the elimination reactions are *anti* under acidic conditions and *syn* under basic conditions. This stereoselectivity is the result of a cyclic mechanism under basic conditions, whereas under acidic conditions an acyclic β -elimination occurs.

The *anti* elimination can also be achieved by converting the β -silyl alcohols to trifluoroacetate esters.²⁷³ The stereoselectivity of the Peterson olefination depends on the generation of pure *syn* or *anti* β -silyl alcohols, so several strategies have been developed for their stereoselective preparation.²⁷⁴

There can be significant differences in the rates of elimination of the stereoisomeric β -hydroxysilanes. Van Vranken and co-workers took advantage of such a situation to achieve a highly stereoselective synthesis of a styryl terpene. (The lithiated reactant is prepared by reductive lithiation; see p. 625). The *syn* adduct decomposes rapidly at -78°C but because of steric effects, the *anti* isomer remains unreacted. Acidification then promotes *anti* elimination to the desired *E*-isomer.²⁷⁵

Scheme 2.19 provides some examples of the Peterson olefination. The Peterson olefination has not been used as widely in synthesis as the Wittig and Wadsworth-Emmons reactions, but it has been used advantageously in the preparation of relatively

unstable olefins. Entries 1 to 8 show the use of lithio silanes having a range of anion-stabilizing groups. The anions are prepared using alkylolithium reagents or lithium amides. Entries 9 to 11 illustrate the utility of the reaction to prepare relatively unstable substituted alkenes. The silyl anions are typically more reactive than stabilized Wittig ylides, and in the case of Entry 12 good results were obtained while the triphenylphosphonium ylide was unreactive. Entry 13 shows the use of Peterson olefination for chain extension with an α-methyl-α,β-unsaturated aldehyde. The preferred reagent for this transformation is a lithio β-trialkylsilylenamine.²⁷⁶

2.4.3. The Julia Olefination Reaction

The *Julia olefination* involves the addition of a sulfonyl-stabilized carbanion to a carbonyl compound, followed by elimination to form an alkene.²⁷⁷ In the initial versions of the reaction, the elimination was done under *reductive conditions*. More recently, a modified version that avoids this step was developed. The former version is sometimes referred to as the *Julia-Lythgoe olefination*, whereas the latter is called the *Julia-Kocienski olefination*. In the reductive variant, the adduct is usually acylated and then treated with a reducing agent, such as sodium amalgam or samarium diiodide.²⁷⁸

Taniguchi, and Y. Yokunaga, *Synlett*, 895 (1994); I. E. Marko, F. Murphy, and S. Dolan, *Tetrahedron Lett.*, **37**, 2089 (1996); I. E. Marko, F. Murphy, L. Kumps, A. Ates, R. Touillaux, D. Craig, S. Carballeas, and S. Dolan, *Tetrahedron*, **57**, 2609 (2001).

In the modified procedure one of several heteroaromatic sulfones is used. The crucial role of the heterocyclic ring is to provide a nonreductive mechanism for the elimination step, which occurs by an addition-elimination mechanism that results in fragmentation to the alkene. The original example used a benzothiazole ring,²⁷⁹ but more recently tetrazoles have been developed for this purpose.²⁸⁰

Other aryl sulfones that can accommodate the nucleophilic addition step also react in the same way. For example, excellent results have been obtained using 3,5-bis-(trifluoromethyl)phenyl sulfones.²⁸¹

As is the case with the Wittig and Peterson olefinations, there is more than one point at which the stereoselectivity of the reaction can be determined, depending on the details of the mechanism. Adduct formation can be product determining or reversible. Furthermore, in the reductive mechanism, there is the potential for stereorandomization if radical intermediates are involved. As a result, there is a degree of variability in the stereoselectivity. Fortunately, the modified version using tetrazolyl sulfones usually gives a predominance of the *E*-isomer.

Scheme 2.20 gives some examples of the application of the Julia olefination in synthesis. Entry 1 demonstrates the reductive elimination conditions. This reaction gave a good *E*:*Z* ratio under the conditions shown. Entry 2 is an example of the use of the modified reaction that gave a good *E*:*Z* ratio in the synthesis of vinyl chlorides. Entry 3 uses the tetrazole version of the reaction in the synthesis of a long-chain ester. Entries 4 to 7 illustrate the use of modified conditions for the synthesis of polyfunctional molecules.

The reactions in this section correspond to the general Pathway **D** discussed earlier (p. 64), in which the carbon nucleophile contains a potential leaving group. This group can be the same or a different group from the anion-stabilizing group. One group of reagents that reacts according to this pattern are the sulfonium ylides, which react with carbonyl compounds to give epoxides.

There are related reactions in which the sulfur is at the sulfoxide or sulfilimine oxidation level. Another example of the addition-cyclization route involves α -haloesters, which react to form epoxides by displacement of the halide ion.

2.5.1. Sulfur Ylides and Related Nucleophiles

Sulfur ylides have several applications as reagents in synthesis.²⁸² Dimethylsulfonium methylide and dimethylsulfoxonium methylide are particularly useful.²⁸³ These sulfur ylides are prepared by deprotonation of the corresponding sulfonium salts, both of which are commercially available.

Whereas phosphonium ylides normally react with carbonyl compounds to give alkenes, dimethylsulfonium methylide and dimethylsulfoxonium methylide yield epoxides. Instead of a four-center elimination, the adducts from the sulfur ylides undergo intramolecular displacement of the sulfur substituent by oxygen. In this reaction, the sulfur substituent serves both to promote anion formation and as the leaving group.

²⁸². B. M. Trost and L. S. Melvin, Jr., *Sulfur Ylides*, Academic Press, New York, 1975; E. Block, *Reactions of Organosulfur Compounds*, Academic Press, New York, 1978.

²⁸³. E. J. Corey and M. Chaykovsky, *J. Am. Chem. Soc.*, **87**, 1353 (1965).

Dimethylsulfonium methylide is both more reactive and less stable than dimethylsulfoxonium methylide, so it is generated and used at a lower temperature. A sharp distinction between the two ylides emerges in their reactions with α,β -unsaturated carbonyl compounds. Dimethylsulfonium methylide yields epoxides, whereas dimethylsulfoxonium methylide reacts by conjugate addition and gives cyclopropanes (compare Entries 5 and 6 in Scheme 2.21). It appears that the reason for the difference lies in the relative rates of the two reactions available to the betaine intermediate: (a) reversal to starting materials, or (b) intramolecular nucleophilic displacement.²⁸⁴ Presumably both reagents react most rapidly at the carbonyl group. In the case of dimethylsulfonium methylide the intramolecular displacement step is faster than the reverse of the addition, and epoxide formation takes place.

With the more stable dimethylsulfoxonium methylide, the reversal is relatively more rapid and product formation takes place only after conjugate addition.

Another difference between dimethylsulfonium methylide and dimethylsulfoxonium methylide concerns the stereoselectivity in formation of epoxides from cyclohexanones. Dimethylsulfonium methylide usually adds from the axial direction whereas dimethylsulfoxonium methylide favors the equatorial direction. This result may also be due to reversibility of addition in the case of the sulfoxonium methylide.⁹² The product from the sulfonium ylide is the result the kinetic preference for axial addition by small nucleophiles (see Part A, Section 2.4.1.2). In the case of reversible addition of the sulfoxonium ylide, product structure is determined by the rate of displacement and this may be faster for the more stable epoxide.

²⁸⁴ C. R. Johnson, C. W. Schroeck, and J. R. Shanklin, *J. Am. Chem. Soc.*, **95**, 7424 (1973).

Examples of the use of dimethylsulfonium methylide and dimethylsulfoxonium methylide are listed in Scheme 2.21. Entries 1 to 5 are conversions of carbonyl compounds to epoxides. Entry 6 is an example of cyclopropanation with dimethylsulfoxonium methylide. Entry 7 compares the stereochemistry of addition of dimethylsulfonium methylide to dimethylsulfoxonium methylide for norborn-5-en-2-one. The product in Entry 8 was used in a synthesis of α -tocopherol (vitamin E).

Sulfur ylides can also transfer substituted methylene units, such as isopropylidene (Entries 10 and 11) or cyclopropylidene (Entries 12 and 13). The oxaspiropentanes formed by reaction of aldehydes and ketones with diphenylsulfonium cyclopropylidene are useful intermediates in a number of transformations such as acid-catalyzed rearrangement to cyclobutanones.²⁸⁵

Aside from the methylide and cyclopropylidene reagents, the sulfonium ylides are not very stable. A related group of reagents derived from sulfoximines offers greater versatility in alkylidene transfer reactions.²⁸⁶ The preparation and use of this class of ylides is illustrated below.

A similar pattern of reactivity has been demonstrated for the anions formed by deprotonation of *S*-alkyl-*N*-*p*-toluenesulfoximines (see Entry 14 in Scheme 2.21).²⁸⁷

The sulfoximine group provides anion-stabilizing capacity in a chiral environment and a number of synthetic applications have been developed based on these properties.²⁸⁸

Dimethylsulfonium methyllide reacts with reactive alkylating reagents such as allylic and benzylic bromides to give terminal alkenes. A similar reaction occurs with primary alkyl bromides in the presence of LiI. The reaction probably involves alkylation of the ylide, followed by elimination.²⁸⁹

²⁸⁹ L. Alcaraz, J. J. Harnett, C. Mioskowski, J. P. Martel, T. LeGall, D.-S. Shin, and J. R. Falck, *Tetrahedron Lett.*, **35**, 5453 (1994).

2.5.2. Nucleophilic Addition-Cyclization of α -Haloesters

The pattern of nucleophilic addition at a carbonyl group followed by intramolecular nucleophilic displacement of a leaving group present in the nucleophile can also be recognized in a much older synthetic technique, the *Darzens reaction*.²⁹⁰ The first step in this reaction is addition of the enolate of the α -haloester to the carbonyl compound. The alkoxide oxygen formed in the addition then effects nucleophilic attack, displacing the halide and forming an α, β -epoxy ester (also called a glycidic ester).

Scheme 2.22 shows some examples of the Darzens reaction.

Trimethylsilylepoxydes can be prepared by an addition-cyclization process. Reaction of chloromethyltrimethylsilane with *sec*-butyllithium at very low temperature gives an α -chloro lithium reagent that leads to an epoxide on reaction with an aldehyde or ketone.²⁹¹

The previous sections dealt with reactions in which the new carbon-carbon bond is formed by addition of the nucleophile to a carbonyl group. Another important method for alkylation of carbon nucleophiles involves addition to an electrophilic multiple bond. The electrophilic reaction partner is typically an α,β -unsaturated ketone, aldehyde, or ester, but other electron-withdrawing substituents such as nitro, cyano, or sulfonyl also activate carbon-carbon double and triple bonds to nucleophilic attack. The reaction is called *conjugate addition* or the *Michael reaction*.

More generally, many combinations of EWG substituents can serve as the anion-stabilizing and alkene-activating groups. Conjugate addition has the potential to form a bond α to one group and β to the other to form a α,γ -disubstituted system.

The scope of the conjugate addition reaction can be further expanded by use of Lewis acids in conjunction with enolate equivalents, especially silyl enol ethers and silyl ketene acetals. The adduct is stabilized by a new bond to the Lewis acid and products are formed from the adduct.

Other kinds of nucleophiles such as amines, alkoxides, and sulfide anions also react with electrophilic alkenes, but we focus on the carbon-carbon bond forming reactions.

2.6.1. Conjugate Addition of Enolates

Conjugate addition of enolates under some circumstances can be carried out with a catalytic amount of base. All the steps are reversible.

When the EWG is a carbonyl group, there can be competition with 1,2-addition, which is especially likely for aldehydes but can also occur with ketones. With successively less reactive carbonyl groups, 1,4-addition becomes more favorable. Highly reactive, hard nucleophiles tend to favor 1,2-addition and the reaction is irreversible if the nucleophile is a poor leaving group. For example with organometallic reagents, 1,2-addition is usually observed and it is irreversible because there is no tendency to expel an alkyl anion. Section 2.6.5 considers some exceptions in which organometallic reagents are added in the 1,4-manner. With less basic nucleophiles, the 1,2-addition is more easily reversible and the 1,4-addition product is usually more stable.

Retrosynthetically, there are inherently two possible approaches to the products of conjugate addition as represented below, where Y and Z represent two different anion-stabilizing groups.

When a catalytic amount of base is used, the most effective nucleophiles are enolates derived from relatively acidic compounds such as β -ketoesters or malonate esters. The adduct anions are more basic than the nucleophile and are protonated under the reaction conditions.

Scheme 2.23 provides some examples of conjugate addition reactions. Entry 1 illustrates the tendency for reaction to proceed through the more stable enolate. Entries 2 to 5 are typical examples of addition of doubly stabilized enolates to electrophilic alkenes. Entries 6 to 8 are cases of addition of nitroalkanes. Nitroalkanes are comparable in acidity to β -ketoesters (see Table 1.1) and are often excellent nucleophiles for conjugate addition. Note that in Entry 8 fluoride ion is used as the base. Entry 9 is a case of adding a zinc enolate (Reformatsky reagent) to a nitroalkene. Entry 10 shows an enamine as the carbon nucleophile. All of these reactions were done under equilibrating conditions.

The fluoride ion is an effective catalyst for conjugate additions involving relatively acidic carbon nucleophiles.²⁹² The reactions can be done in the presence of excess

fluoride, where the formation of the $[F-H-F]^-$ ion occurs, or by use of a tetralkylammonium fluoride in an aprotic solvent.

Ref. 293

Ref. 294

As in the case of aldol addition, the scope of conjugate addition reactions can be extended by the use of techniques for regio- and stereospecific preparation of enolates and enolate equivalents. If the reaction is carried out with a stoichiometrically formed enolate in the absence of a proton source, the initial product is the enolate of the adduct. The replacement of a π bond by a σ bond ensures a favorable ΔH .

Among Michael acceptors that have been shown to react with ketone and ester enolates under kinetic conditions are methyl α -trimethylsilylvinyl ketone,²⁹⁵ methyl α -methylthioacrylate,²⁹⁶ methyl methylthiovinyl sulfoxide,²⁹⁷ and ethyl α -cyanoacrylate.²⁹⁸ Each of these acceptors benefits from a second anion-stabilizing substituent. The latter class of acceptors has been found to be capable of generating contiguous quaternary carbon centers.

Ref. 298

Several examples of conjugate addition of carbanions carried out under aprotic conditions are given in Scheme 2.24. The reactions are typically quenched by addition of a proton source to neutralize the enolate. It is also possible to trap the adduct by silylation or, as we will see in Section 2.6.2, to carry out a tandem alkylation. Lithium enolates preformed by reaction with LDA in THF react with enones to give 1,4-diketones (Entries 1 and 2). Entries 3 and 4 involve addition of ester enolates to enones. The reaction in Entry 3 gives the 1,2-addition product at -78°C but isomerizes to the 1,4-product at 25°C . Esters of 1,5-dicarboxylic acids are obtained by addition of ester enolates to α,β -unsaturated esters (Entry 5). Entries 6 to 8 show cases of

enolate addition to acceptors with two anion-stabilizing groups. Entry 8 is noteworthy in that it creates two contiguous quaternary carbons. Entry 9 shows an addition of an amide enolate. Entry 10 is a case of an enolate stabilized by both the dithiane ring and ester substituent. The acceptor, an α,β -unsaturated lactam, is relatively unreactive but the addition is driven forward by formation of a new σ bond. The chiral moiety incorporated into the five-membered ring promotes enantioselective formation of the new stereocenter.

There have been several studies of the stereochemistry of conjugate addition reactions. If there are substituents on both the nucleophilic enolate and the acceptor, either *syn* or *anti* adducts can be formed.

The reaction shows a dependence on the *E*- or *Z*-stereochemistry of the enolate. *Z*-enolates favor *anti* adducts and *E*-enolates favor *syn* adducts. These tendencies can be understood in terms of an eight-membered chelated TS.²⁹⁹ The enone in this TS is in an *s-cis* conformation. The stereochemistry is influenced by the *s-cis/s-trans* equilibria. Bulky R^4 groups favor the *s-cis* conformer and enhance the stereoselectivity of the reaction. A computational study on the reaction also suggested an eight-membered TS.³⁰⁰

The carbonyl functional groups are the most common both as activating EWG substituents in the acceptor and as the anion-stabilizing group in the enolate, but several other EWGs also undergo conjugate addition reactions. Nitroalkenes are excellent acceptors. The nitro group is a strong EWG and there is usually no competition from nucleophilic attack on the nitro group.

The nitro group can be converted to a ketone by hydrolysis of the nitronate anion, permitting the synthesis of 1,4-dicarbonyl compounds.

Ref. 302

Anions derived from nitriles can act as nucleophiles in conjugate addition reactions. A range of substituted phenylacetonitriles undergoes conjugate addition to 4-phenylbut-3-en-2-one.

The reaction occurs via the 1,2-adduct, which isomerizes to the 1,4-adduct,³⁰³ and there is an energy difference of about 5 kcal/mol in favor of the 1,4-adduct. With the parent compound in THF, the isomerization reaction has been followed kinetically and appears to occur in two phases. The first part of the reaction occurs with a half-life of a few minutes, and the second with a half-life of about an hour. A possible explanation is the involvement of dimeric species, with the homodimer being more reactive than the heterodimer.

A very important extension of the conjugate addition reaction is discussed in Chapter 8. Organocopper reagents have a strong preference for conjugate addition. Organocopper nucleophiles do not require anion-stabilizing substituents, and they allow conjugate addition of alkyl, alkenyl, and aryl groups to electrophilic alkenes.

2.6.2. Conjugate Addition with Tandem Alkylation

When conjugate addition is carried out under aprotic conditions with stoichiometric formation of the enolate, the adduct is present as an enolate until the reaction mixture is quenched with a proton source. It is therefore possible to effect a second reaction of the enolate by addition of an alkyl halide or sulfonate to the solution of the adduct enolate, which results in an alkylation. This reaction sequence permits the formation of two new C–C bonds.

³⁰³. H. J. Reich, M. M. Biddle, and R. J. Edmonston, *J. Org. Chem.*, **70**, 3375 (2005).

Several examples of tandem conjugate addition-alkylation follow.

Ref. 304

Ref. 305

Ref. 306

Tandem conjugate addition-alkylation has proven to be an efficient means of introducing groups at both α - and β -positions at enones.³⁰⁷ As with simple conjugate addition, organocopper reagents are particularly important in this application, and they are discussed further in Section 8.1.2.3.

2.6.3. Conjugate Addition by Enolate Equivalents

Conditions for effecting conjugate addition of neutral enolate equivalents such as silyl enol ethers in the presence of Lewis acids have been developed and are called *Mukaiyama-Michael reactions*. Trimethylsilyl enol ethers can be caused to react with electrophilic alkenes by use of TiCl_4 . These reactions proceed rapidly even at -78°C .³⁰⁸

Ref. 310

Ref. 311

Initial stereochemical studies suggested that the Mukaiyama-Michael reaction proceeds through an open TS, since there was a tendency to favor *anti* diastereoselectivity, regardless of the silyl enol ether configuration.³¹²

The stereoselectivity can be enhanced by addition of $\text{Ti}(\text{O-}i\text{-Pr})_4$. The active nucleophile under these conditions is expected to be an “ate” complex in which a much larger $\text{Ti}(\text{O-}i\text{-Pr})_4$ group replaces Li^+ as the Lewis acid.³¹³ Under these conditions, the *syn:anti* ratio is dependent on the stereochemistry of the enolate.

R	Configuration	<i>anti:syn</i>	Yield(%)
Et	<i>Z</i>	95:5	69
Ph	<i>Z</i>	> 92:8	85
<i>i</i> -Pr	<i>Z</i>	> 97:3	65
<i>i</i> -Pr	<i>E</i>	17:83	91

Silyl acetals of thiol esters have also been studied. With TiCl_4 as the Lewis acid, there is correspondence between the configuration of the silyl thioketene acetal and the adduct stereochemistry.³¹⁴ *E*-Isomers show high *anti* selectivity, whereas *Z*-isomers are less selective.

³¹⁴. Y. Fujita, J. Otera, and S. Fukuzumi, *Tetrahedron*, **52**, 9419 (1996).

Stannyl enolates give good addition yields in the presence of a catalytic amount of $n\text{-(C}_4\text{H}_9)_4\text{N}^+\text{Br}^-$.³¹⁵ The bromide ion plays an active role in this reaction by forming a more reactive species via coordination at the tin atom.

It is believed that this reaction involves the formation of the α -stannyl ester. Metals such as lithium that form ionic enolates would be more likely to reverse the addition step.

Nitroalkenes are also reactive Michael acceptors under Lewis acid-catalyzed conditions. Titanium tetrachloride or stannic tetrachloride can induce addition of silyl enol ethers. The initial adduct is trapped in a cyclic form by trimethylsilylation.³¹⁶ Hydrolysis of this intermediate regenerates the carbonyl group and also converts the *aci*-nitro group to a carbonyl.³¹⁷

Fluoride ion can also induce reaction of silyl ketene acetals with electrophilic alkenes. The fluoride source in these reactions is *tris*-(dimethylamino)sulfonium difluorotrimethylsilicate (TASF).

Ref. 318

Enamines also react with electrophilic alkenes to give conjugate addition products. The addition reactions of enamines of cyclohexanones show a strong preference for attack from the axial direction.³¹⁹ This is anticipated on stereoelectronic grounds because the π orbital of the enamine is the site of nucleophilicity.

Scheme 2.25 shows some examples of additions of enolate equivalents. A range of Lewis acid catalysts has been used in addition to TiCl_4 and SnCl_4 . Entry 1 shows uses of a lanthanide catalyst. Entry 2 employs LiClO_4 as the catalyst. The reaction in Entry 3 includes a chiral auxiliary that controls the stereoselectivity; the chiral auxiliary is released by a cyclization using *N*-methylhydroxylamine. Entries 4 and 5 use the triphenylmethyl cation as a catalyst and Entries 6 and 7 use trimethylsilyl triflate and an enantioselective catalyst, respectively.

2.6.4. Control of Facial Selectivity in Conjugate Addition Reactions

As is the case for aldol addition, chiral auxiliaries and catalysts can be used to control stereoselectivity in conjugate addition reactions. Oxazolidinone chiral auxiliaries have been used in both the nucleophilic and electrophilic components under Lewis acid-catalyzed conditions. *N*-Acyloxazolidinones can be converted to nucleophilic titanium enolates with $\text{TiCl}_3(\text{O}-i\text{-Pr})$.³²⁰

Unsaturated acyl derivatives of oxazolidinones can be used as acceptors, and these reactions are enantioselective in the presence of chiral *bis*-oxazoline catalysts.³²¹ Silyl ketene acetals of thiol esters are good reactants and the stereochemistry depends on the ketene acetal configuration. The *Z*-isomer gives higher diastereoselectivity than the *E*-isomer.

³²¹ D. A. Evans, K. A. Scheidt, J. N. Johnston, and M. C. Willis, *J. Am. Chem. Soc.*, **123**, 4480 (2001).

The above examples contain an ester group that acts as a second activating group. The reactions are also accelerated by including one equivalent of $(\text{CF}_3)_2\text{CHOH}$. This alcohol functions by promoting solvolysis of a dihydropyran intermediate that otherwise inhibits the catalyst.

Alkylidenemalonate esters are also good acceptors in reactions with silyl ketene acetals of thiol esters under very similar conditions.³²²

A number of other chiral catalysts can promote enantioselective conjugate additions of silyl enol ethers, silyl ketene acetals, and related compounds. For example, an oxazaborolidinone derived from allothreonine achieves high enantioselectivity in additions of silyl thioketene acetals.³²³ The optimal conditions for this reaction also include a hindered phenol and an ether additive.

Enantioselectivity has been observed for acyclic ketones, using proline as a catalyst. Under optimum conditions, *ds* > 80% and *e.e.* > 70% were observed.³²⁴ These

reactions presumably involve the proline-derived enamine. (See Section 2.1.5.6 for a discussion of enantioselective reactions of proline enamines.)

Enantioselective additions of β -dicarbonyl compounds to β -nitrostyrenes have been achieved using *bis*-oxazolidine catalysts. This method was used in an enantioselective synthesis of the antidepressant drug rolipram.³²⁵

Enantioselectivity can also be based on structural features present in the reactants. A silyl substituent has been used to control stereochemistry in both cyclic and acyclic systems. The silyl substituent can then be removed by TBAF.³²⁶ As with enolate alkylation (see p. 32), the steric effect of the silyl substituent directs the approach of the acceptor to the opposite face.

³²⁵ D. M. Barnes, J. Ji, M. G. Fickes, M. A. Fitzgerald, S. A. King, H. E. Morton, F. A. Plagge, M. Preskill, S. H. Wagaw, S. J. Wittenberger, and J. Zhang, *J. Am. Chem. Soc.*, **124**, 13097 (2002).

³²⁶ D. Enders and T. Otten, *Synlett*, 747 (1999).

High stereoselectivity is also observed in the addition of an enamine using 2-methoxymethylpyrrolidine as the amine.³²⁷

2.6.5. Conjugate Addition of Organometallic Reagents

There are relatively few examples of organolithium compounds acting as nucleophiles in conjugate addition. Usually, organolithium compounds react at the carbonyl group, to give 1,2-addition products. Here, we consider a few cases of organometallic reagents that give conjugate addition products. There are a very large number of copper-mediated conjugate additions, and we discuss these reactions in Section 8.1.2.3.

Alkyl and aryllithium compounds have been found to undergo 1,4-addition with the salts of α, β -unsaturated acids.³²⁸ This result reflects the much reduced reactivity of the carboxylate carbonyl group as an electrophile.

α, β -Unsaturated amides have been found to be good reactants toward organometallic reagents. These reactions involve the deprotonated amide ion, which is less susceptible to 1,2-addition than ketones and esters.

Ref. 329

Similar reactions have also been observed with tertiary amides and the adducts can be alkylated by tandem S_N2 reactions.

Ref. 330

³³⁰. G. B. Mpango, K. K. Mahalanabis, S. Mahdavi-Damghani, and V. Snieckus, *Tetrahedron Lett.*, **21**, 4823 (1980).

Lithiated *N*-allylcarbamates add to nitroalkenes. In the presence of (–)-sparteine, this reaction is both diastereoselective (*anti*) and enantioselective.³³¹

The enantioselectivity is due to the retention of the chiral sparteine in the lithiated reagent. The adducts have been used to synthesize a number of pyrrolidine and piperidine derivatives.

Several mixed organozinc reagents having a trimethylsilylmethyl group as the nonreacting substituent add to enones under the influence of TMS-Br.³³² The types of groups that can be added include alkyl, aryl, heteroaryl, and certain functionalized alkyl groups, including 5-pivaloyloxypentyl and 3-ethoxycarbonylpropyl.

α,β -Unsaturated aldehydes and esters, as well as nitroalkenes, can also function as acceptors under these conditions. Dialkylzinc reagents add to β -nitrostyrene in the presence of TADDOL-TiCl₂.³³³

2.6.6. Conjugate Addition of Cyanide Ion

Cyanide ion acts as a carbon nucleophile in the conjugate addition reaction. The pK of HCN is 9.3, so addition in hydroxylic solvents is feasible. An alcoholic solution of potassium or sodium cyanide is suitable for simple compounds.

Ref. 334

Cyanide addition has also been done under Lewis acid catalysis. Triethylaluminum-hydrogen cyanide and diethylaluminum cyanide are useful reagents for conjugate

³³⁴. O. R. Rodig and N. J. Johnston, *J. Org. Chem.*, **34**, 1942 (1969).

addition of cyanide. The latter is the more reactive of the two reagents. These reactions presumably involve the coordination of the aluminum reagent at the carbonyl oxygen.

Ref. 335

Ref. 336

Diethylaluminum cyanide mediates conjugate addition of cyanide to α,β -unsaturated oxazolines. With a chiral oxazoline, 30–50% diastereomeric excess can be achieved. Hydrolysis gives partially resolved α -substituted succinic acids. The rather low enantioselectivity presumably reflects the small size of the cyanide ion.

Ref. 337

A chiral aluminum-salen catalyst gives good enantioselectivity in the addition of cyanide (from TMS-CN) to unsaturated acyl imides.³³⁸

Problems

(References for these problems will be found on page 1272.)

2.1 Predict the product formed in each of the following reactions:

(a) $\text{CH}_3\text{CO}_2\text{C}(\text{CH}_3)_3 \rightarrow (\text{CH}_3)_2\text{C}(\text{OH})\text{CO}_2\text{C}(\text{CH}_3)_3$

(b) $\text{THPO}(\text{CH}_2)_3\text{CH}=\text{O} \rightarrow \text{THPO}(\text{CH}_2)_3\text{CH}=\text{CHCH}_2\text{OH}$

(c)  $\text{Cyclohexanone} \rightarrow \text{Cyclohex-2-en-1-ol}$

(d)  $\text{Ph}_2\text{C}=\text{O} \rightarrow \text{Ph}_2\text{C}(\text{CN})\text{CO}_2\text{C}_2\text{H}_5$

(e)  $\text{2-Octanone} \rightarrow \text{2-Ethyl-2-octanone}$

(f)  $\text{2-Oxocyclohexanecarbaldehyde} \rightarrow \text{2-Oxocyclohexanecarboxaldehyde}$

2.3. Step-by-step retrosynthetic analysis of each of the target molecules reveals that they can be efficiently prepared in a few steps from the starting material shown on the right. Do a retrosynthetic analysis and suggest reagents and reaction conditions for carrying out the desired synthesis.

2.4. Offer a mechanism for each of the following reactions:

2.5. Tetraacetic acid (or a biological equivalent) is suggested as an intermediate in the biosynthesis of phenolic natural products. In the laboratory, it can be readily converted to orsellinic acid. Suggest a mechanism for this reaction under the conditions specified.

2.6. a. A stereospecific method for deoxygenating epoxides to alkenes involves reaction of the epoxide with the diphenylphosphide ion, followed by methyl iodide. The method results in overall inversion of alkene stereochemistry. Thus, *cis*-cyclooctene epoxide gives *trans*-cyclooctene. Propose a mechanism for this reaction and discuss its relationship to the Wittig reaction.

- b. Reaction of the epoxide of *E*-4-octene (*trans*-2,3-dipropyloxirane) with potassium trimethylsilylanide gives *Z*-4-octene as the only alkene product in 93% yield. Suggest a reasonable mechanism for this reaction.

- 2.7. a. A fairly general method for ring closure has been developed that involves vinyltriphenylphosphonium halides as reactants. Indicate the mechanism of this reaction, as applied to the two examples shown below. Suggest two other types of rings that could be synthesized using vinyltriphenylphosphonium salts.

- b. Allylphosphonium salts were used as a synthon in the synthesis of cyclohexadienes. Suggest an appropriate co-reactant and other reagents that would be expected to lead to cyclohexadienes.

- c. The product shown below is formed by the reaction of vinyltriphenylphosphonium bromide, the lithium enolate of cyclohexanone, and 1,3-diphenyl-2-propen-1-one. Formulate a mechanism.

- d. The dimethoxy phosphonylmethylcyclopentenone shown below has been used as a starting material for the synthesis of prostaglandin analogs such as **7A**. The reaction involves formation of the anion, reaction with an alkyl halide, and a Wadsworth-Emmons reaction. What reactivity of the anion makes this approach feasible?

- e. The reagent **7B** has found use in the expeditious construction of more complex molecules from simple starting materials. For example, the enolate of 3-pentanone when treated first with **7B** and then with benzaldehyde gives **7C**

as a 2:1 mixture of stereoisomers. Explain the mechanism by which this reaction occurs.

- f. The reagent **7D** converts enolates of aldehydes into cyclohexadienyl phosphonates **7E**. Write a mechanism for this reaction. What alternative products might have been observed?

- 2.8. Compounds **8A** and **8B** were key intermediates in an early total synthesis of cholesterol. Rationalize their formation by the routes shown.

- 2.9. The first few steps in a synthesis of the alkaloid conessine produce **9B**, starting from **9A**. Suggest a sequence of reactions for effecting this conversion.

- 2.10. A substance known as elastase is involved in various inflammatory diseases such as arthritis, pulmonary emphysema, and pancreatitis. Elastase activity can be inhibited by a compound known as elasnin, obtained from a microorganism.

A synthesis of elasin has been reported that utilizes compound **10A** as a key intermediate. Suggest a synthesis of **10A** from methyl hexanoate and hexanal.

- 2.11. Treatment of compound **11A** with LDA followed by cyclohexanone can give either **11B** or **11C**. Compound **11B** is formed when the aldehyde is added at -78°C , whereas **11C** is formed if the aldehyde is added at 0°C . Treatment of **11B** with LDA at 0°C gives **11C**. Explain these results.

- 2.12. Dissect the following molecules into potential precursors by locating all bonds that could be made by intramolecular aldol or conjugate addition reactions. Suggest possible starting materials and conditions for performing the desired reactions.

- 2.13. Mannich condensations permit one-step reactions to form the following substances from substantially less complex starting materials. Identify a potential starting material that would give rise to the product shown in a single step under Mannich reaction conditions.

- 2.14. Indicate whether or not the aldol reactions shown below would be expected to exhibit high stereoselectivity. Show the stereochemistry of the expected product(s).

2.15. Suggest transition structures that would account for the observed stereoselectivity of the following reactions.

2.16. Suggest starting materials and reaction conditions suitable for obtaining each of the following compounds by a procedure involving conjugate addition.

- (a) 4,4-dimethyl-5-nitropentan-2-one
 (b) diethyl 2,3-diphenylglutarate
 (c) ethyl 2-benzoyl-4-(2-pyridyl)butanoate
 (d) 2-phenyl-3-oxocyclohexanecarboxylic acid

2.17. In the synthesis of a macrolide **17A**, known as latrunculin A, the intermediate **17B** was assembled from components **17C**, **17D**, and **17E** in a “one-pot” tandem process. By a retrosynthetic analysis, show how the synthesis could occur and identify a sequence of reactions and corresponding reagents.

2.18. The tricyclic substance **18A** and **18B** are both potential synthetic intermediates for synthesis of the biologically active diterpene forskolin. These intermediates can be prepared from the monocyclic precursors shown. Indicate the nature of the reactions involved in these transformations.

2.19. Account for the course of the following reactions:

- a. Substituted acetophenones react with ethyl phenylpropynoate under basic conditions to give pyrones. Formulate a mechanism for this reaction.

- b. The reaction of simple ketones such as 2-butanone or 1-phenyl-2-propanone with α,β -unsaturated ketones gives cyclohexanone on heating with methanol containing potassium methoxide. Indicate how the cyclohexanones could be formed. Can more than one isomeric cyclohexanone be formed? Can you suggest a means for distinguishing between possible cyclohexanones?
- c. α -Benzoyloxyphenylacetonitrile reacts with acrylonitrile in the presence of NaH to give 2-cyano-1,4-diphenylbutane-2,4-dione.

- d. Reaction of the lithium anion of 3-methoxy-2-methylcyclopentanone with methyl acrylate gives the two products shown as an 82:18 mixture. Alkaline hydrolysis of the mixture gives a single pure product. How is the minor product formed and how is it converted to the hydrolysis product?

2.20. Explain the stereochemical outcome of the following reactions.

a.

b.

Functional Group Interconversion by Substitution, Including Protection and Deprotection

Introduction

Chapters 1 and 2 dealt with formation of new carbon-carbon bonds by reactions in which one carbon acts as the nucleophile and another as the electrophile. In this chapter we turn our attention to noncarbon nucleophiles. Nucleophilic substitution is used in a variety of interconversions of functional groups. We discuss substitution at both sp^3 carbon and carbonyl groups. Substitution at saturated carbon usually involves the S_N2 mechanism, whereas substitution at carbonyl groups usually occurs by addition-elimination.

Substitution at saturated carbons

Substitution at carbonyl groups

The mechanistic aspects of nucleophilic substitutions at saturated carbon and carbonyl centers were considered in Part A, Chapters 4 and 7, respectively. In this chapter we discuss some of the important synthetic transformations that involve these types of

reactions. Section 3.1 considers conversion of alcohols to reactive alkylating agents and Section 3.2 discusses the use of S_N2 reactions for various functional group transformations. Substitution reactions can also be used to *break* bonds for synthetic purposes, and Section 3.3 deals with cleavage of C—O bonds in ethers and esters by S_N2 and S_N1 reactions. The carbonyl substitution reactions that interconvert the acyl halides, acid anhydrides, esters, and carboxamides are discussed in Section 3.4. Often, manipulation of protecting groups also involves nucleophilic substitution and carbonyl exchange reactions. We discuss protection and deprotection of the most common functional groups in Section 3.5.

3.1. Conversion of Alcohols to Alkylating Agents

3.1.1. Sulfonate Esters

Alcohols are a very important compounds for synthesis. However, because the hydroxide ion is a very poor leaving group, alcohols are not reactive as alkylating agents. They can be activated to substitution by O-protonation, but the acidity that is required is incompatible with most nucleophiles except those, such as the halides, that are anions of strong acids. The preparation of sulfonate esters from alcohols is an effective way of installing a reactive leaving group on an alkyl chain. The reaction is very general and complications arise only if the resulting sulfonate ester is sufficiently reactive to require special precautions. *p*-Toluenesulfonate (*tosylate*) and methanesulfonate (*mesylate*) esters are used most frequently for preparative work, but the very reactive trifluoromethanesulfonates (*triflates*) are useful when an especially good leaving group is required. The usual method for introducing tosyl or mesyl groups is to allow the alcohol to react with the sulfonyl chloride in pyridine at 0°–25° C.¹ An alternative method is to convert the alcohol to a lithium salt, which is then allowed to react with the sulfonyl chloride.²

Trifluoromethanesulfonates of alkyl and allylic alcohols can be prepared by reaction with trifluoromethanesulfonic anhydride in halogenated solvents in the presence of pyridine.³ Since the preparation of sulfonate esters does not disturb the C—O bond, problems of rearrangement or racemization do not arise in the ester formation step. However, sensitive sulfonate esters, such as allylic systems, may be subject to reversible ionization reactions, so appropriate precautions must be taken to ensure structural and stereochemical integrity. Tertiary alkyl sulfonates are neither as easily prepared nor as stable as those from primary and secondary alcohols. Under the standard preparative conditions, tertiary alcohols are likely to be converted to the corresponding alkene.

3.1.2. Halides

The prominent role of alkyl halides in the formation of carbon-carbon bonds by enolate alkylation was evident in Chapter 1. The most common precursors for alkyl halides are the corresponding alcohols and a variety of procedures have been developed for this transformation. The choice of an appropriate reagent is usually dictated by the sensitivity of the alcohol and any other functional groups present in the molecule. In some cases, the hydrogen halides can be used. Unsubstituted primary alcohols can be converted to bromides with hot concentrated hydrobromic acid.⁴ Alkyl chlorides can be prepared by reaction of primary alcohols with hydrochloric acid–zinc chloride.⁵ Owing to the harsh conditions, these procedures are only applicable to very acid-stable molecules. These reactions proceed by the S_N2 mechanism and elimination, and rearrangements are not a problem for primary alcohols. Reactions of hydrogen halides with tertiary alcohols proceed by the S_N1 mechanism, so these reactions are preparatively useful only when the carbocation intermediate is unlikely to give rise to rearranged product.⁶ In general, these methods are suitable only for simple, unfunctionalized alcohols.

Another general method for converting alcohols to halides involves reactions with halides of certain nonmetallic elements. Thionyl chloride, phosphorus trichloride, and phosphorus tribromide are the most common examples of this group of reagents. These reagents are suitable for alcohols that are neither acid sensitive nor prone to structural rearrangement. The reaction of alcohols with thionyl chloride initially results in the formation of a chlorosulfite ester. There are two mechanisms by which the chlorosulfite can be converted to a chloride. In aprotic nucleophilic solvents, such as dioxane, solvent participation can lead to overall retention of configuration.⁷

In the absence of solvent participation, chloride attack on the chlorosulfite ester leads to product with inversion of configuration.

Primary and secondary alcohols are rapidly converted to chlorides by a 1:1 mixture of SOCl_2 and benzotriazole in an inert solvent such as CH_2Cl_2 .⁸

⁸ S. S. Chaudhari and K. G. Akamanchi, *Synlett*, 1763 (1999).

This reagent combination also converts carboxylic acids to acyl chlorides (see Section 3.4.1). The mechanistic basis for the special effectiveness of benzotriazole has not yet been determined, but it seems likely that nucleophilic catalysis is involved. Sulfinyl ester intermediates may be involved, because *Z*-2-butene-1,4-diol gives a cyclic sulfite ester with one equivalent of reagent but the dichloride with two equivalents.

Reaction with the hindered secondary alcohol menthol stops at the dialkyl sulfite ester. The examples reported do not establish the stereochemistry of the reaction.

The mechanism for the reactions of alcohols with phosphorus halides can be illustrated using phosphorus tribromide. Initial reaction between the alcohol and phosphorus tribromide leads to a trialkyl phosphite ester by successive displacements of bromide. The reaction stops at this stage if it is run in the presence of an amine, which neutralizes the hydrogen bromide that is formed.⁹ If the hydrogen bromide is not neutralized, the phosphite ester is protonated and each alkyl group is converted to the halide by nucleophilic substitution by bromide ion. The driving force for cleavage of the C–O bond is the formation of a strong phosphoryl double bond.

As C–Br bond formation occurs by back-side attack, inversion of the configuration at carbon is anticipated. However, both racemization and rearrangement are observed as competing processes.¹⁰ For example, conversion of 2-butanol to 2-butyl bromide with PBr_3 is accompanied by 10–13% racemization and a small

⁹ A. H. Ford-Moore and B. J. Perry, *Org. Synth.*, **IV**, 955 (1963).

¹⁰ H. R. Hudson, *Synthesis*, 112 (1969).

amount of *t*-butyl bromide is also formed.¹¹ The extent of rearrangement increases with increasing chain length and branching.

Ref. 12

Ref. 13

Owing to the acidic conditions, these methods are limited to acid-stable molecules. Milder reagents are necessary for many functionally substituted alcohols. A very general and important method for activating alcohols toward nucleophiles is by converting them to *alkoxyphosphonium ions*.¹⁴ The trivalent phosphorus reagents are activated by reaction with a halogen or related electrophile, and the alkoxyphosphonium ions are very reactive toward nucleophilic attack, with the driving force for substitution being formation of the strong phosphoryl bond.

A variety of reagents can function as the electrophile E^+ in the general mechanism. The most useful synthetic procedures for preparation of halides are based on the halogens, positive halogens sources, and diethyl azodicarboxylate. A 1:1 adduct formed from triphenylphosphine and bromine converts alcohols to bromides.¹⁵ The alcohol displaces bromide ion from the pentavalent adduct, giving an alkoxyphosphonium intermediate. The phosphonium ion intermediate then undergoes nucleophilic attack by bromide ion, forming triphenylphosphine oxide.

The alkoxy phosphonium intermediate is formed by a reaction that does not break the C—O bond and the second step proceeds by back-side displacement on carbon, so the stereochemistry of the overall process is inversion.

Ref. 16

2,4,4,6-Tetrabromocyclohexa-2,5-dienone is also a useful bromine source.

Ref. 17

Triphenylphosphine dichloride exhibits similar reactivity and can be used to prepare chlorides.¹⁸ The most convenient methods for converting alcohols to chlorides are based on in situ generation of chlorophosphonium ions¹⁹ by reaction of triphenylphosphine with various chlorine compounds such as carbon tetrachloride²⁰ or hexachloroacetone.²¹ These reactions involve formation of chlorophosphonium ions.

The chlorophosphonium ion then reacts with the alcohol to give an alkoxyphosphonium ion that is converted to the chloride.

Several modifications of procedures based on halophosphonium ion have been developed. Triphenylphosphine and imidazole in combination with iodine or bromine gives good conversion of alcohols to iodides or bromides.²² An even more reactive system consists of chlorodiphenylphosphine, imidazole, and the halogen,²³ and has the further advantage that the resulting phosphorus by-product diphenylphosphinic acid, can be extracted with base during product workup.

A very mild procedure for converting alcohols to iodides uses triphenylphosphine, diethyl azodicarboxylate (DEAD), and methyl iodide.²⁴ This reaction occurs

with clean inversion of stereochemistry.²⁵ The key intermediate is again an alkoxyphosphonium ion.

The role of the DEAD is to activate the triphenylphosphine toward nucleophilic attack by the alcohol. In the course of the reaction the N=N double bond is reduced. As is discussed later, this method is applicable for activation of alcohols to substitution by other nucleophiles in addition to halide ions. The activation of alcohols to nucleophilic attack by the triphenylphosphine-DEAD combination is called the *Mitsunobu reaction*.²⁶

A very mild method that is useful for compounds that are prone to allylic rearrangement involves prior conversion of the alcohol to the tosylate, followed by nucleophilic displacement with halide ion.

Another very mild procedure involves reaction of the alcohol with the heterocyclic 2-chloro-3-ethylbenzoxazolium cation.²⁸ The alcohol adds to the electrophilic heterocyclic ring, displacing chloride. The alkoxy group is thereby activated toward a nucleophilic substitution that forms a stable product, 3-ethylbenzoxazolinone.

The reaction can be used for making either chlorides or bromides by using the appropriate tetraalkylammonium salt as a halide source.

Scheme 3.1 gives some examples of the various alcohol to halide conversions that have been discussed. Entries 1 and 2 are examples of synthesis of primary bromides using PBr_3 . Entry 3 is an example of synthesis of a chloride using $\text{Ph}_3\text{P}-\text{Cl}_2$. The reactant, neopentyl alcohol, is often resistant to nucleophilic substitution and prone to rearrangement, but reacts well under these conditions. Entries 4 and 5 illustrate the use of halogenated solvents as chlorine sources in Ph_3P -mediated reactions. The reactions in Entries 6 and 7 involve synthesis of bromides by nucleophilic substitution on tosylates. The reactant in Entry 7 is prone to rearrangement via ring expansion,

but no rearrangement was observed under these conditions. Entry 8 illustrates the use of a chlorobenzoxazolium cation for conversion of a secondary alcohol to a chloride. This reaction was shown to proceed with inversion of configuration. Entry 9 involves conversion of a primary alcohol to a chloride using SOCl_2 . In this particular example, the tertiary amino group captures the HCl that is formed by the reaction of the alcohol with SOCl_2 . There is also some suggestion from the procedure that much of the reaction proceeds through a chlorosulfite intermediate. After the reactants are mixed (exothermic reaction), the material is heated in ethanol, during which time gas evolution occurs. This suggests that much of the chlorosulfite ester survives until the heating stage.

Entry 10 illustrates the application of the Mitsunobu reaction to synthesis of a steroidal iodide and demonstrates that inversion occurs. Entry 11 shows the use of the isolated $\text{Ph}_3\text{P}-\text{Br}_2$ complex. The reaction in Entry 12 involves the preparation of a primary iodide using the $\text{Ph}_3\text{P}-\text{I}_2$ -imidazole reagent combination.

3.2. Introduction of Functional Groups by Nucleophilic Substitution at Saturated Carbon

The mechanistic aspects of nucleophilic substitution reactions were treated in detail in Chapter 4 of Part A. That mechanistic understanding has contributed to the development of nucleophilic substitution reactions as important synthetic processes. Owing to its stereospecificity and avoidance of carbocation intermediates, the $\text{S}_\text{N}2$ mechanism is advantageous from a synthetic point of view. In this section we discuss

the role of S_N2 reactions in the preparation of several classes of compounds. First, however, it is desirable to review the important role that solvent plays in S_N2 reactions. The knowledgeable manipulation of solvent and related medium effects has led to significant improvement of many synthetic procedures that proceed by the S_N2 mechanism.

3.2.1. General Solvent Effects

The objective in selecting the reaction conditions for a preparative nucleophilic substitution is to enhance the mutual reactivity of the leaving group and nucleophile so that the desired substitution occurs at a convenient rate and with minimal competition from other possible reactions. The generalized order of leaving-group reactivity $\text{RSO}_3^- \sim \text{I}^- > \text{Br}^- > \text{Cl}^-$ pertains for most S_N2 processes. (See Section 4.2.3 of Part A for more complete data.) Mesylates, tosylates, iodides, and bromides are all widely used in synthesis. Chlorides usually react rather slowly, except in especially reactive systems, such as allyl and benzyl.

The overall synthetic objective normally governs the choice of the nucleophile. Optimization of reactivity therefore must be achieved by selection of the reaction conditions, particularly the solvent. Several generalizations about solvents can be made. Hydrocarbons, halogenated hydrocarbons, and ethers are usually unsuitable solvents for reactions involving ionic metal salts. Acetone and acetonitrile are somewhat more polar, but the solubility of most ionic compounds in these solvents is low. Solubility can be considerably improved by use of salts of cations having substantial hydrophobic character, such as those containing tetraalkylammonium ions. Alcohols are reasonably good solvents for salts, but the nucleophilicity of hard anions is relatively low in alcohols because of extensive solvation. The polar aprotic solvents, particularly dimethylformamide (DMF) and dimethylsulfoxide (DMSO), are good solvents for salts and, by virtue of selective cation solvation, anions usually show enhanced nucleophilicity in these solvents. Hexamethylphosphoric triamide (HMPA), *N,N*-dimethylacetamide, and *N*-methylpyrrolidinone are other examples of polar aprotic solvents.²⁹ The high water solubility of these solvents and their high boiling points can sometimes cause problems in product separation and purification. Furthermore, HMPA is toxic. In addition to enhancing reactivity, polar aprotic solvents also affect the order of reactivity of nucleophilic anions. In DMF the halides are all of comparable nucleophilicity,³⁰ whereas in hydroxylic solvents the order is $\text{I}^- > \text{Br}^- > \text{Cl}^-$ and the differences in reactivity are much greater.³¹

There are two other approaches to enhancing reactivity in nucleophilic substitutions by exploiting solvation effects on reactivity: the use of *crown ethers* as catalysts and the utilization of *phase transfer conditions*. The crown ethers are a family of cyclic polyethers, three examples of which are shown below.

15-crown-5

18-crown-6

dicyclohexano-18-crown-6

The first number designates the ring size and the second the number of oxygen atoms in the ring. By complexing the cation in the cavity of the crown ether, these compounds can solubilize salts in nonpolar solvents. In solution, the anions are more reactive as nucleophiles because they are weakly solvated. Tight ion pairing is also precluded by the complexation of the cation by the nonpolar crown ether. As a result, nucleophilicity approaches or exceeds that observed in aprotic polar solvents,³² but the crown ethers do present some hazards. They are toxic and also have the potential to transport toxic anions, such as cyanide, through the skin.

Another method of accelerating nucleophilic substitution is to use phase transfer catalysts,³³ which are ionic substances, usually quaternary ammonium or phosphonium salts, in which the hydrocarbon groups in the cation are large enough to convey good solubility in nonpolar solvents. In other words, the cations are highly *lipophilic*. Phase transfer catalysis usually is done in a two-phase system. The reagent is dissolved in a water-insoluble solvent such as a hydrocarbon or halogenated hydrocarbon. The salt of the nucleophile is dissolved in water. Even with vigorous mixing, such systems show little tendency to react, because the nucleophile and reactant remain separated in the water and organic phases, respectively. When a phase transfer catalyst is added, the lipophilic cations are transferred to the nonpolar phase and anions are attracted from the water to the organic phase to maintain electrical neutrality. The anions are weakly solvated in the organic phase and therefore exhibit enhanced nucleophilicity. As a result, the substitution reactions proceed under relatively mild conditions. The salts of the nucleophile are often used in high concentration in the aqueous solution and in some procedures the solid salts are used.

3.2.2. Nitriles

The replacement of a halide or sulfonate by cyanide ion, extending the carbon chain by one atom and providing an entry to carboxylic acid derivatives, has been a reaction of synthetic importance since the early days of organic chemistry. The classical conditions for preparing nitriles involve heating a halide with a cyanide salt in aqueous alcohol solution.

Halpern, *Phase Transfer Catalysis: Fundamentals, Applications and Industrial Perspective*, Chapman and Hall, New York, 1994.

Ref. 34

Ref. 35

These reactions proceed more rapidly in polar aprotic solvents. In DMSO, for example, primary alkyl chlorides are converted to nitriles in 1 h or less at temperatures of 120°–140° C.³⁶ Phase transfer catalysis by hexadecyltributylphosphonium bromide permits conversion of 1-chlorooctane to octyl cyanide in 95% yield in 2 h at 105° C.³⁷

Catalysis by 18-crown-6 of the reaction of solid potassium cyanide with a variety of chlorides and bromides has been demonstrated.³⁸ With primary bromides, yields are high and reaction times are 15–30 h at reflux in acetonitrile (83° C). Interestingly, the chlorides are more reactive and require reaction times of only about 2 h. Secondary halides react more slowly and yields drop because of competing elimination. Tertiary halides do not react satisfactorily because elimination dominates.

3.2.3. Oxygen Nucleophiles

The oxygen nucleophiles that are of primary interest in synthesis are the hydroxide ion (or water), alkoxide ions, and carboxylate anions, which lead, respectively, to alcohols, ethers, and esters. Since each of these nucleophiles can also act as a base, reaction conditions are selected to favor substitution over elimination. Usually, a given alcohol is more easily obtained than the corresponding halide so the halide-to-alcohol transformation is not used extensively for synthesis. The hydrolysis of benzyl halides to the corresponding alcohols proceeds in good yield. This can be a useful synthetic transformation because benzyl halides are available either by side chain halogenation or by the chloromethylation reaction (Section 11.1.3).

³⁸ F. L. Cook, C. W. Bowers, and C. L. Liotta, *J. Org. Chem.*, **39**, 3416 (1974).

Ether formation from alkoxides and alkylating reagents is a reaction of wide synthetic importance. The conversion of phenols to methoxyaromatics, for example, is a very common reaction. Methyl iodide, methyl tosylate, or dimethyl sulfate can be used as the alkylating agents. The reaction proceeds in the presence of a weak base, such as Na_2CO_3 or K_2CO_3 , which deprotonates the phenol. The conjugate bases of alcohols are considerably more basic than phenoxides, so β -elimination can be a problem. Phase transfer conditions can be used in troublesome cases.⁴⁰ Fortunately, the most useful and commonly encountered ethers are methyl and benzyl ethers, where elimination is not a problem and the corresponding halides are especially reactive toward substitution.

Two methods for converting carboxylic acids to esters fall into the mechanistic group under discussion: the reaction of carboxylic acids with diazo compounds, especially diazomethane and alkylation of carboxylate anions by halides or sulfonates. The esterification of carboxylic acids with diazomethane is a very fast and clean reaction.⁴¹ The alkylating agent is the extremely reactive methyldiazonium ion, which is generated by proton transfer from the carboxylic acid to diazomethane. The collapse of the resulting ion pair with loss of nitrogen is extremely rapid.

The main drawback to this reaction is the toxicity of diazomethane and some of its precursors. Diazomethane is also potentially explosive. Trimethylsilyldiazomethane is an alternative reagent,⁴² which is safer and frequently used in preparation of methyl esters from carboxylic acids.⁴³ Trimethylsilyldiazomethane also O-methylates alcohols.⁴⁴ The latter reactions occur in the presence of fluoroboric acid in dichloromethane.

Especially for large-scale work, esters may be more safely and efficiently prepared by reaction of carboxylate salts with alkyl halides or tosylates. Carboxylate anions are not very reactive nucleophiles so the best results are obtained in polar aprotic solvents⁴⁵ or with crown ether catalysts.⁴⁶ The reactivity order for carboxylate salts is $\text{Na}^+ < \text{K}^+ < \text{Rb}^+ < \text{Cs}^+$. Cesium carboxylates are especially useful in polar aprotic solvents. The enhanced reactivity of the cesium salts is due to both high solubility and minimal ion pairing with the anion.⁴⁷ Acetone is a good solvent for reaction of carboxylate anions with alkyl iodides.⁴⁸ Cesium fluoride in DMF is another useful

combination.⁴⁹ Carboxylate alkylation procedures are particularly advantageous for preparation of hindered esters, which can be relatively difficult to prepare by the acid-catalyzed esterification method (Fisher esterification), which we discuss in Section 3.4.

During the course of synthesis, it is sometimes necessary to invert the configuration at an oxygen-substituted center. One of the best ways of doing this is to activate the hydroxy group to substitution by a carboxylate anion. The activation is frequently done using the Mitsunobu reaction.⁵⁰ Hydrolysis of the resulting ester give the alcohol of inverted configuration.

Ref. 51

Ref. 52

Carboxylate anions derived from somewhat stronger acids, such as *p*-nitrobenzoic acid and chloroacetic acid, seem to be particularly useful in this Mitsunobu inversion reaction.⁵³ Inversion can also be carried out on sulfonate esters using cesium carboxylates and DMAP as a catalyst in toluene.⁵⁴ The effect of the DMAP seems to involve complexation and solubilization of the cesium salts.

Sulfonate esters also can be prepared under Mitsunobu conditions. Use of zinc tosylate in place of the carboxylic acid gives a tosylate of inverted configuration.

Ref. 55

The Mitsunobu conditions also can be used to effect a variety of other important and useful nucleophilic substitution reactions, such as conversion of alcohols to mixed phosphite esters.⁵⁶ The active phosphitylating agent is believed to be a mixed phosphoramidite.

Mixed phosphonate acid esters can also be prepared from alkylphosphonate monoesters, although here the activation is believed occur at the alcohol.⁵⁷

3.2.4. Nitrogen Nucleophiles

The alkylation of neutral amines by halides is complicated from a synthetic point of view by the possibility of multiple alkylation that can proceed to the quaternary ammonium salt in the presence of excess alkyl halide.

Even with a limited amount of the alkylating agent, the equilibria between protonated product and the neutral starting amine are sufficiently fast that a mixture of products may be obtained. For this reason, when monoalkylation of an amine is desired, the reaction is usually best carried out by *reductive amination*, a reaction that is discussed in Chapter 5. If complete alkylation to the quaternary salt is desired, use of excess alkylating agent and a base to neutralize the liberated acid normally results in complete reaction.

Amides are weakly nucleophilic and react only slowly with alkyl halides. The anions of amides are substantially more reactive. The classical Gabriel procedure for synthesis of amines from phthalimide is illustrative.⁵⁸

⁵⁷ D. A. Campbell, *J. Org. Chem.*, **57**, 6331 (1992); D. A. Campbell and J. C. Bermak, *J. Org. Chem.*, **59**, 658 (1994).

⁵⁹ P. L. Salzberg and J. V. Supniewski, *Org. Synth.*, **I**, 119 (1932).

The enhanced acidity of the NH group in phthalimide permits formation of the anion, which is readily alkylated by alkyl halides or tosylates. The amine can then be liberated by reaction of the substituted phthalimide with hydrazine.

Ref. 60

It has been found that the deprotection phase of the Gabriel synthesis is accelerated by inclusion of NaOH.⁶¹

Secondary amides can be alkylated on nitrogen by using sodium hydride for deprotonation, followed by reaction with an alkyl halide.⁶²

Neutral tertiary and secondary amides react with very reactive alkylating agents, such as triethyloxonium tetrafluoroborate, to give O-alkylation.⁶³ The same reaction occurs, but more slowly, with tosylates and dimethyl sulfate. Neutralization of the resulting salt provides iminoethers.

Sulfonamides are relatively acidic and their anions can serve as nitrogen nucleophiles.⁶⁴ Sulfonamido groups can be introduced at benzylic positions with a high level of inversion under Mitsunobu conditions.⁶⁵

Proline analogs can be obtained by cyclization of δ -hydroxyalkylamino acid carbamates.

Mitsunobu conditions are effective for glycosylation of weak nitrogen nucleophiles, such as indoles. This reaction has been used in the synthesis of antitumor compounds.

Azides are useful intermediates for synthesis of various nitrogen-containing compounds. They can also be easily reduced to primary amines and undergo cycloaddition reactions, as is discussed in Section 6.2. Azido groups are usually introduced into aliphatic compounds by nucleophilic substitution.⁶⁹ The most reliable procedures involve heating an appropriate halide with sodium azide in DMSO⁷⁰ or DMF.⁷¹ Alkyl azides can also be prepared by reaction in high-boiling alcohols.⁷²

Phase transfer conditions are used as well for the preparation of azides.⁷³

Tetramethylguanidinium azide, an azide salt that is readily soluble in halogenated solvents, is a useful source of azide ions in the preparation of azides from reactive halides such as α -haloketones, α -haloamides, and glycosyl halides.⁷⁴

There are also useful procedures for preparation of azides directly from alcohols. Reaction of alcohols with 2-fluoro-1-methylpyridinium iodide followed by reaction with lithium azide gives good yields of alkyl azides.⁷⁵

Diphenylphosphoryl azide reacts with alcohols in the presence of triphenylphosphine and DEAD.⁷⁶ Hydrazoic acid, HN_3 , can also serve as the azide ion source under these conditions.⁷⁷ These reactions are examples of the Mitsunobu reaction.

Diphenylphosphoryl azide also gives good conversion of primary alkyl and secondary benzylic alcohols to azides in the presence of the strong organic base diazabicycloundecane (DBU). These reactions proceed by O-phosphorylation followed by $\text{S}_\text{N}2$ displacement.⁷⁸

This reaction can be extended to secondary alcohols with the more reactive *bis*-(4-nitrophenyl)phosphorazidate.⁷⁹

3.2.5. Sulfur Nucleophiles

Anions derived from thiols are strong nucleophiles and are easily alkylated by halides.

Neutral sulfur compounds are also good nucleophiles, Sulfides and thioamides readily form salts with methyl iodide, for example.

Even sulfoxides, in which nucleophilicity is decreased by the additional oxygen, can be alkylated by methyl iodide. These sulfoxonium salts have useful synthetic applications as discussed in Section 2.5.1.

3.2.6. Phosphorus Nucleophiles

Both neutral and anionic phosphorus compounds are good nucleophiles toward alkyl halides. We encountered examples of these reactions in Chapter 2 in connection with the preparation of the valuable phosphorane and phosphonate intermediates used for Wittig reactions.

The reaction with phosphite esters is known as the *Michaelis-Arbuzov reaction* and proceeds through an unstable trialkoxyphosphonium intermediate. The second stage is another example of the great tendency of alkoxyphosphonium ions to react with nucleophiles to break the O—C bond, resulting in formation of a phosphoryl P=O bond.

3.2.7. Summary of Nucleophilic Substitution at Saturated Carbon

Some of the nucleophilic substitution reactions at sp^3 carbon that are most valuable for synthesis were outlined in the preceding sections, and they all fit into the general mechanistic patterns that were discussed in Chapter 4 of Part A. The order of reactivity of alkylating groups is benzyl \sim allyl $>$ methyl $>$ primary $>$ secondary. Tertiary halides and sulfonates are generally not satisfactory because of the preference for elimination over S_N2 substitution. Owing to their high reactivity toward nucleophilic substitution, α -haloesters, α -haloketones, and α -halonitriles are usually favorable reactants for substitution reactions. The reactivity of leaving groups is sulfonate \sim iodide $>$ bromide $>$ chloride. Steric hindrance decreases the rate of nucleophilic substitution. Thus projected synthetic steps involving nucleophilic substitution must be evaluated for potential steric problems.

Scheme 3.2 gives some representative examples of nucleophilic substitution processes drawn from *Organic Syntheses* and from other synthetic efforts. Entries 1 to 3 involve introduction of cyano groups via tosylates and were all conducted in polar aprotic solvents. Entries 4 to 8 are examples of introduction of the azido functional group by substitution. The reaction in Entry 4 was done under phase transfer conditions. A concentrated aqueous solution of NaN_3 was heated with the alkyl bromide and 5 mol % methyltriocetylammmonium chloride. Entries 5 to 7 involve introduction of the azido group at secondary carbons with inversion of configuration in each case. The reactions in Entries 7 and 8 involve formation of phosphoryl esters as intermediates. These conditions were found preferable to the Mitsunobu conditions for the reaction in Entry 7. The electron-rich benzylic reactant gave both racemization and elimination via a carbocation intermediate under the Mitsunobu conditions. Entries 9 and 10 are cases of controlled alkylation of amines. In the reaction in Entry 9, the pyrrolidine was used in twofold excess. The ester EWGs have a rate-retarding effect that slows further alkylation to the quaternary salt. In the reaction in Entry 10, the monohydrochloride of piperazine is used as the reactant. The reaction was conducted in ethanol, and the dihydrochloride salt of the product precipitates as reaction proceeds, which helps minimize quaternization or N,N' -dialkylation. The yield of the dihydrochloride is 97–99%, and that of the amine is 65–75% after neutralization of the salt and distillation. The reaction in Entry 11 is the O-alkylation of an amide. The reaction was done in refluxing benzene, and the product was obtained by distillation after the neutralization.

Sections D through H of Scheme 3.2 involve oxygen nucleophiles. The hydrolysis reactions in Entries 12 and 13 both involve benzylic positions. The reaction site in Entry 13 is further activated by the ERG substituents on the ring. Entries 14 to 17 are examples of base-catalyzed ether formation. The selectivity of the reaction in Entry 17 for the *meta*-hydroxy group is an example of a fairly common observation in aromatic systems. The *ortho*-hydroxy group is more acidic and probably also stabilized by chelation, making it less reactive.

Dialkylation occurs if a stronger base (NaOH) and dimethyl sulfate is used. Entry 18 is a typical diazomethane methylation of a carboxylic acid. The toxicity of diazomethane

and its precursors, as well as the explosion hazard of diazomethane, requires that all recommended safety precautions be taken. Entries 19 to 21 involve formation of esters by alkylation of carboxylate salts. The reaction in Entry 19 was done in the presence of 5 mol % 18-crown-6. A number of carboxylic acids, including pivalic acid as shown in the example, were alkylated in high yield under these conditions. Entry 20 shows the alkylation of the rather hindered mesitoic acid by a secondary iodide. These conditions also gave high yields for unhindered acids and iodides. Entry 21 involves formation of a methyl ester using CH_3I and KF as the base in DMF. Entry 22 involves formation of a sulfonate ester under Mitsunobu conditions with clean inversion of configuration. The conditions reported represent the optimization of the reaction as part of the synthesis of an antihypertensive drug, fosinopril.

Sections I and J of Scheme 3.2 show reactions with sulfur and phosphorus nucleophiles. The reaction in Entry 25 is a useful method for introducing thiol groups. The solid thiourea is a convenient source of sulfur. A thiuronium ion is formed and this avoids competition from formation of a dialkyl sulfide. The intermediate is readily hydrolyzed by base.

3.3. Cleavage of Carbon-Oxygen Bonds in Ethers and Esters

The cleavage of carbon-oxygen bonds in ethers or esters by nucleophilic substitution is frequently a useful synthetic transformation.

The alkoxide group is a poor leaving group and carboxy is only slightly better. As a result, these reactions usually require assistance from a protic or Lewis acid. The classical ether cleavage conditions involving concentrated hydrogen halides are much too strenuous for most polyfunctional molecules, so several milder reagents have been developed,⁸⁶ including boron tribromide,⁸⁷ dimethylboron bromide,⁸⁸ trimethylsilyl iodide,⁸⁹ and boron trifluoride in the presence of thiols.⁹⁰ The mechanism for ether cleavage with boron tribromide involves attack of bromide ion on an adduct formed

from the ether and the electrophilic boron reagent. The cleavage step can occur by either an S_N2 or an S_N1 process, depending on the structure of the alkyl group.

Good yields are generally observed, especially for methyl ethers. The combination of boron tribromide with dimethyl sulfide has been found to be particularly effective for cleaving aryl methyl ethers.⁹¹

The boron trifluoride-alkyl thiol reagent combination also operates on the basis of nucleophilic attack on an oxonium ion generated by reaction of the ether with boron trifluoride.⁹⁰

Trimethylsilyl iodide (TMSI) cleaves methyl ethers in a period of a few hours at room temperature.⁸⁹ Benzyl and *t*-butyl systems are cleaved very rapidly, whereas secondary systems require longer times. The reaction presumably proceeds via an initially formed silyl oxonium ion.

The direction of cleavage in unsymmetrical ethers is determined by the relative ease of O—R bond breaking by either S_N2 (methyl, benzyl) or S_N1 (*t*-butyl) processes. As trimethylsilyl iodide is rather expensive, alternative procedures that generate the reagent in situ have been devised.

Allylic ethers are cleaved in a matter of a few minutes by TMSI under in situ conditions.

Ref. 94

Diiodosilane, SiH_2I_2 , is an especially effective reagent for cleaving secondary alkyl ethers.⁹⁵

TMSI also effects rapid cleavage of esters. The cleavage step involves iodide attack on the O-silylated ester. The first products formed are trimethylsilyl esters, but these are hydrolyzed rapidly on exposure to water.⁹⁶

Benzyl, methyl, and *t*-butyl esters are rapidly cleaved, but secondary esters react more slowly. In the case of *t*-butyl esters, the initial silylation is followed by a rapid ionization to the *t*-butyl cation.

Ether cleavage can also be effected by reaction with acetic anhydride and Lewis acids such as BF_3 , FeCl_3 , and MgBr_2 .⁹⁷ Mechanistic investigations point to acylium ions generated from the anhydride and Lewis acid as the reactive electrophile.

Scheme 3.3 gives some specific examples of ether and ester cleavage reactions. Entries 1 and 2 illustrate the use of boron tribromide for ether cleavage. The reactions are conducted at dry ice-acetone temperature and the exposure to water on workup hydrolyzes residual O–B bonds. In the case of Entry 2, the primary hydroxy group that is deprotected lactonizes spontaneously. The reaction in Entry 3 uses HBr in acetic acid to cleave a methyl aryl ether. This reaction was part of a scale-up of the synthesis of a drug candidate molecule. Entries 4 to 6 are examples of the cleavage of ethers and esters using TMSI. The selectivity exhibited in Entry 6 for

cleavage of the more hindered of the two ether groups may reflect a steric acceleration of the nucleophilic displacement step.

Entries 7 to 9 illustrate the use of the $\text{BF}_3\text{-EtSH}$ reagent combination. The reaction in Entry 9 was described as “troublesome in the extreme.” The problem is that the ether is both a primary benzylic ether and a secondary one, the latter associated with a ring having several ERG substituents. Electrophilic conditions lead to preferential cleavage of the secondary benzylic bond and formation of elimination products. The reaction was done successfully in the presence of excess NaOAc , which presumably allows the nucleophilic $\text{S}_\text{N}2$ cleavage of the primary benzyl bond to dominate by reducing the reactivity of the electrophilic species that are present. The cleavage of the cyclic ether shown in Entry 10 occurs with inversion of configuration at the reaction site, as demonstrated by the *trans* stereochemistry of the product. When applied to 2-substituted tetrahydrofurans, the reaction gives mainly cleavage of the $\text{C}(5)\text{-O}$ bond, indicating that steric access of the nucleophilic component of the reaction is dominant in determining regioselectivity.

Entry 11 illustrates a cleavage reaction using an acylating agent in conjunction with a Lewis acid.

3.4. Interconversion of Carboxylic Acid Derivatives

The classes of compounds that are conveniently considered together as derivatives of carboxylic acids include the acyl chlorides, carboxylic acid anhydrides, esters, and amides. In the case of simple aliphatic and aromatic acids, synthetic transformations

among these derivatives are usually straightforward, involving such fundamental reactions as ester saponification, formation of acyl chlorides, and the reactions of amines with acid anhydrides or acyl chlorides to form amides. The mechanisms of these reactions are discussed in Section 7.4 of Part A.

When a multistep synthesis is being undertaken with other sensitive functional groups present in the molecule, milder reagents and reaction conditions may be necessary. As a result, many alternative methods for effecting interconversion of the carboxylic acid derivatives have been developed and some of the most useful reactions are considered in the succeeding sections.

3.4.1. Acylation of Alcohols

The traditional method for transforming carboxylic acids into reactive acylating agents capable of converting alcohols to esters or amines to amides is by formation of the acyl chloride. Molecules devoid of acid-sensitive functional groups can be converted to acyl chlorides with thionyl chloride or phosphorus pentachloride. When milder conditions are necessary, the reaction of the acid or its sodium salt with oxalyl chloride provides the acyl chloride. When a salt is used, the reaction solution remains essentially neutral.

Ref. 98

This reaction involves formation of a mixed anhydride-chloride of oxalic acid, which then decomposes, generating both CO_2 and CO .

Treatment of carboxylic acids with half an equivalent of oxalyl chloride can generate anhydrides.⁹⁹

⁹⁸. M. Miyano and C. R. Dorn, *J. Org. Chem.*, **37**, 268 (1972).

⁹⁹. R. Adams and L. H. Urich, *J. Am. Chem. Soc.*, **42**, 599 (1920).

Carboxylic acids can be converted to acyl chlorides and bromides by a combination of triphenylphosphine and a halogen source. Triphenylphosphine and carbon tetrachloride convert acids to the corresponding acyl chloride.¹⁰⁰ Similarly, carboxylic acids react with the triphenyl phosphine-bromine adduct to give acyl bromides.¹⁰¹ Triphenylphosphine-*N*-bromosuccinimide also generates acyl bromide in situ.¹⁰² All these reactions involve acyloxyphosphonium ions and are mechanistically analogous to the alcohol-to-halide conversions that are discussed in Section 3.1.2.

Acyl chlorides are highly reactive acylating agents and react very rapidly with alcohols and other nucleophiles. Preparative procedures often call for use of pyridine as a catalyst. Pyridine catalysis involves initial formation of an acyl pyridinium ion, which then reacts with the alcohol. Pyridine is a better nucleophile than the neutral alcohol, but the acyl pyridinium ion reacts more rapidly with the alcohol than the acyl chloride.¹⁰³

An even stronger catalytic effect is obtained when 4-dimethylaminopyridine (DMAP) is used.¹⁰⁴ The dimethylamino group acts as an electron donor, increasing both the nucleophilicity and basicity of the pyridine nitrogen.

The inclusion of DMAP to the extent of 5–20 mol % in acylations by acid anhydrides and acyl chlorides increases acylation rates by up to four orders of magnitude and permits successful acylation of tertiary and other hindered alcohols. The reagent combination of an acid anhydride with MgBr_2 and a hindered tertiary amine, e.g., $(i\text{-Pr})_2\text{NC}_2\text{H}_5$ or 1,2,2,6,6,-pentamethylpiperidine, gives an even more reactive acylation system, which is useful for hindered and sensitive alcohols.¹⁰⁵

Another efficient catalyst for acylation is $\text{Sc}(\text{O}_3\text{SCF}_3)_3$, which can be used in combination with anhydrides¹⁰⁶ and other reactive acylating agents¹⁰⁷ and is a mild reagent for acylation of tertiary alcohols. Mechanistic investigation of $\text{Sc}(\text{O}_3\text{SCF}_3)_3$ -catalyzed acylation indicates that triflic acid is involved. Acylation is stopped by the presence of a sterically hindered base such as 2,6-di-(*t*-butyl)-4-methylpyridine. The active acylating agent appears to be the acyl triflate. Two catalytic cycles operate. Cycle 2 requires only triflic acid, whereas Cycle 1 involves both the scandium salt and triflic acid.¹⁰⁸

The acylation of tertiary alcohols can be effected by use of $\text{Sc}(\text{O}_3\text{SCF}_3)_3$ with diisopropylcarbodiimide (D-*i*-PCI) and DMAP.¹⁰⁹

This method was effective for acylation of a hindered tertiary alcohol in the anticancer agent camptothecin by protected amino acids.

Ref. 110

Lanthanide triflates have similar catalytic effects. $\text{Yb}(\text{O}_3\text{SCF}_3)_3$ and $\text{Lu}(\text{O}_3\text{SCF}_3)_3$, for example, were used in selective acylation of 10-deacetylbaccatin III, an important intermediate for preparation of the antitumor agent paclitaxel.¹¹¹

Scandium triflimidate, $\text{Sc}[\text{N}(\text{SO}_2\text{CF}_3)_2]_3$, is also a very active acylation catalyst.

Ref. 112

Bismuth(III) triflate is also a powerful acylation catalyst that catalyzes reactions with acetic anhydride and other less reactive anhydrides such as benzoic and pivalic anhydrides.¹¹³ Good results are achieved with tertiary and hindered secondary alcohols, as well as with alcohols containing acid- and base-sensitive functional groups.

Trimethylsilyl triflate is also a powerful catalyst for acylation by anhydrides. Reactions of alcohols with a modest excess (1.5 equiv) of anhydride proceed in inert solvents at 0°C . Even tertiary alcohols react rapidly.¹¹⁴ The active acylation reagent is presumably generated by O-silylation of the anhydride.

In addition to acyl halides and acid anhydrides, there are a number of milder and more selective acylating agents that can be readily prepared from carboxylic acids. Imidazolides, the *N*-acyl derivatives of imidazole, are examples.¹¹⁵ Imidazolides are isolable substances and can be prepared directly from the carboxylic acid by reaction with carbonyldiimidazole.

Two factors are responsible for the reactivity of the imidazolides as acylating reagents. One is the relative weakness of the “amide” bond. Owing to the aromatic character of imidazole nitrogens, there is little of the $N \rightarrow C=O$ delocalization that stabilizes normal amides. The reactivity of the imidazolides is also enhanced by protonation of the other imidazole nitrogen, which makes the imidazole ring a better leaving group.

Imidazolides can also be activated by N-alkylation with methyl triflate.¹¹⁶ Imidazolides react with alcohols on heating to give esters and react at room temperature with amines to give amides. Imidazolides are particularly appropriate for acylation of acid-sensitive materials.

Dicyclohexylcarbodiimide (DCCI) is an example of a reagent that converts carboxylic acids to reactive acylating agents. This compound has been widely applied in the acylation step in the synthesis of polypeptides from amino acids¹¹⁷ (see also Section 13.3.1). The reactive species is an *O*-acyl isourea. The acyl group is highly reactive because the nitrogen is susceptible to protonation and the cleavage of the acyl-oxygen bond converts the carbon-nitrogen double bond of the isourea to a more stable carbonyl group.¹¹⁸

The combination of carboxyl activation by DCCI and catalysis by DMAP provides a useful method for in situ activation of carboxylic acids for reaction with alcohols. The reaction proceeds at room temperature.¹¹⁹

2-Chloropyridinium¹²⁰ and 3-chloroisoxazolium¹²¹ cations also activate carboxy groups toward nucleophilic attack. In each instance the halide is displaced from the heterocycle by the carboxylate via an addition-elimination mechanism. Nucleophilic attack on the activated carbonyl group results in elimination of the heterocyclic ring, with the departing oxygen being converted to an amidelike structure. The positive

charge on the heterocyclic ring accelerates both the initial addition step and the subsequent elimination of the heterocycle.

Carboxylic acid esters of thiols are considerably more reactive as acylating reagents than the esters of alcohols. Particularly reactive are esters of pyridine-2-thiol because there is an additional driving force in the formation of the more stable pyridine-2-thione tautomer.

Additional acceleration of acylation can be obtained by inclusion of cupric salts, which coordinate at the pyridine nitrogen. This modification is useful for the preparation of highly hindered esters.¹²² Pyridine-2-thiol esters can be prepared by reaction of the carboxylic acid with 2,2'-dipyridyl disulfide and triphenylphosphine¹²³ or directly from the acid and 2-pyridyl thiochloroformate.¹²⁴

The 2-pyridyl and related 2-imidazolyl disulfides have found special use in the closure of large lactone rings.¹²⁵ Structures of this type are encountered in a number of antibiotics and other natural products and require mild conditions for cyclization because numerous other sensitive functional groups are present. It has been suggested that the pyridyl and imidazolyl thioesters function by a mechanism in which the heterocyclic nitrogen acts as a base, deprotonating the alcohol group. This proton transfer provides a cyclic TS in which hydrogen bonding can enhance the reactivity of the carbonyl group.¹²⁶

Good yields of large ring lactones are achieved by this method.

Use of 2,4,6-trichlorobenzoyl chloride, Et_3N , and DMAP, known as the *Yamaguchi method*,¹²⁸ is frequently used to effect macrolactonization. The reaction is believed to involve formation of the mixed anhydride with the acyl chloride, which then forms an acyl pyridinium ion on reaction with DMAP.¹²⁹

Intramolecular lactonization can also be carried out with DCCl and DMAP. As with most other macrolactonizations, the reactions must be carried out in rather dilute solution to promote the intramolecular cyclization in competition with intermolecular reaction, which leads to dimers or higher oligomers. A study with 15-hydroxypentadecanoic acid demonstrated that a proton source is beneficial under these conditions and found the hydrochloride of DMAP to be convenient.¹³⁰

Scheme 3.4 gives some typical examples of the preparation and use of active acylating agents from carboxylic acids. Entries 1 and 2 show generation of acyl chlorides by reaction of carboxylic acids or salts with oxalyl chloride. Entry 3 shows a convenient preparation of 2-pyridylthio esters, which are themselves potential acylating agents (see p. 248). Entries 4 to 6 employ various coupling agents to form esters. Entries 7 and 8 illustrate acylations catalyzed by DMAP. Entries 9 to 13 are

examples of macrocyclizations. Entry 9 uses the di-2-pyridyl disulfide- Ph_3P method. The cyclization was done in approximately 0.02 *M* acetonitrile by dropwise addition of the disulfide. Entries 10 and 11 are examples of application of the Yamaguchi macrolactonization procedure via the mixed anhydride with 2,4,6-trichlorobenzoyl chloride. The reaction in Entry 12 uses BOP-Cl as the coupling reagent. This particular reagent gave the best results among the several alternatives that were explored. Further discussion of this reagent can be found in Section 13.3.1. Entry 13 is an example of the use of the DCCI-DMAP reagent combination.

3.4.2. Fischer Esterification

As noted in the preceding section, one of the most general methods of synthesis of esters is by reaction of alcohols with an acyl chloride or other activated carboxylic acid derivative. Section 3.2.5 dealt with two other important methods, namely, reactions with diazoalkanes and reactions of carboxylate salts with alkyl halides or sulfonate esters. There is also the acid-catalyzed reaction of carboxylic acids with alcohols, which is called the *Fischer esterification*.

This is an equilibrium process and two techniques are used to drive the reaction to completion. One is to use a large excess of the alcohol, which is feasible for simple and inexpensive alcohols. The second method is to drive the reaction forward by irreversible removal of water, and azeotropic distillation is one way to accomplish this. Entries 1 to 4 in Scheme 3.5 are examples of acid-catalyzed esterifications. Entry 5 is the preparation of a diester starting with an anhydride. The initial opening of the anhydride ring is followed by an acid-catalyzed esterification.

3.4.3. Preparation of Amides

The most common method for preparation of amides is the reaction of ammonia or a primary or secondary amine with one of the reactive acylating reagents described in Section 3.4.1. Acid anhydrides give rapid acylation of most amines and are convenient if available. However, only one of the two acyl groups is converted to an amide. When acyl halides are used, some provision for neutralizing the hydrogen halide that is formed is necessary because it will react with the amine to form the corresponding salt. The *Schotten-Baumann conditions*, which involve shaking an amine with excess anhydride or acyl chloride and an alkaline aqueous solution, provide a very satisfactory method for preparation of simple amides.

Ref. 131

A great deal of work has been done on the in situ activation of carboxylic acids toward nucleophilic substitution by amines. This type of reaction is fundamental for synthesis of polypeptides (see also Section 13.3.1). Dicyclohexylcarbodiimide

(DCCI) is often used for coupling carboxylic acids and amines to give amides. Since amines are better nucleophiles than alcohols, the leaving group in the acylation reagent need not be as reactive as is necessary for alcohols. The *p*-nitrophenyl¹³² and 2,4,5-trichlorophenyl¹³³ esters of amino acids are sufficiently reactive toward amines to be useful in amide synthesis. Acyl derivatives of *N*-hydroxysuccinimide are also useful for synthesis of peptides and other types of amides.^{134, 135} Like the *p*-nitrophenyl esters, the acylated *N*-hydroxysuccinimides can be isolated and purified, but react rapidly with free amino groups.

The *N*-hydroxysuccinimide that is liberated is easily removed because of its solubility in dilute base. The relative stability of the anion of *N*-hydroxysuccinimide is also responsible for the acyl derivative being reactive toward nucleophilic attack by an

amino group. Esters of *N*-hydroxysuccinimide are also used to carry out chemical modification of peptides, proteins, and other biological molecules by acylation of nucleophilic groups in these molecules. For example, detection of estradiol antibodies can be accomplished using an estradiol analog to which a fluorescent label has been attached.

Ref. 136

Similarly, photolabels, such as 4-azidobenzoylglycine can be attached to peptides and used to detect binding sites in proteins.¹³⁷

1-Hydroxybenzotriazole is also useful in conjunction with DCC.¹³⁸ For example, Boc-protected leucine and the methyl ester of phenylalanine can be coupled in 88% yield with these reagents.

Ref. 139

Carboxylic acids can also be activated by the formation of mixed anhydrides with various phosphoric acid derivatives. Diphenyl phosphoryl azide, for example, is an effective reagent for conversion of amines to amides.¹⁴⁰ The proposed mechanism involves formation of the acyl azide as a reactive intermediate.

Another useful reagent for amide formation is compound **1**, known as BOP-Cl,¹⁴¹ which also proceeds by formation of a mixed carboxylic phosphoric anhydride.

Another method for converting esters to amides involves aluminum amides, which can be prepared from trimethylaluminum and the amine. These reagents convert esters directly to amides at room temperature.¹⁴²

The driving force for this reaction is the strength of the aluminum-oxygen bond relative to the aluminum-nitrogen bond. This reaction provides a good way of making synthetically useful amides of *N*-methoxy-*N*-methylamine.¹⁴³ Trialkylaminotin and *bis*-(hexamethyldisilylamido)tin amides, as well as *tetrakis*-(dimethylamino)titanium, show similar reactivity.¹⁴⁴ These reagents can also catalyze exchange reactions between amines and amides under moderate conditions.¹⁴⁵ For example, whereas exchange of benzylamine into *N*-phenylheptanamide occurs very slowly at 90°C in the absence of catalyst (> months), the conversion is effected in 16 h by $\text{Ti}[\text{N}(\text{CH}_3)_2]_4$.

Tris-(dimethylamino)aluminum also promotes similar exchange reactions. The catalysis by titanium and aluminum amides may involve bifunctional catalysis in which the metal center acts as a Lewis acid while also delivering the nucleophilic amide.

Interestingly, $\text{Sc}(\text{O}_3\text{SCF}_3)_3$ is also an active catalyst for these exchange reactions.

The cyano group is at the carboxylic acid oxidation level, so nitriles are potential precursors of primary amides. Partial hydrolysis is sometimes possible.¹⁴⁶

A milder procedure involves the reaction of a nitrile with an alkaline solution of hydrogen peroxide.¹⁴⁷ The strongly nucleophilic hydrogen peroxide adds to the nitrile and the resulting adduct gives the amide. There are several possible mechanisms for the subsequent decomposition of the peroxycarboximidic adduct.¹⁴⁸

In all the mechanisms, the hydrogen peroxide is converted to oxygen and water, leaving the organic substrate hydrolyzed, but at the same oxidation level.

Scheme 3.6 illustrates some of the means of preparation of amides. Entries 1 and 2 are cases of preparation of simple amides by conversion of the carboxylic acid to an acyl chloride using SOCl_2 . Entry 3 is the acetylation of glycine by acetic anhydride. The reaction is done in concentrated aqueous solution ($\sim 3\text{ M}$) using a twofold excess of the anhydride. The reaction is exothermic and the product crystallizes from the reaction mixture when it is cooled. Entries 4 and 5 are ester aminolysis reactions. The cyano group is an activating group for the ester in Entry 4, and this reaction occurs at room temperature in concentrated ammonia solution. The reaction in Entry 5 involves a less nucleophilic and more hindered amine, but involves a relatively reactive aryl ester. A much higher temperature is required for this reaction. Entries 6 to 8 illustrate the use of several of the coupling reagents for preparation of amides. Entries 9 and 10 show preparation of primary amides by hydrolysis of nitriles. The first reaction involves partial hydrolysis, whereas the second is an example of peroxide-accelerated hydrolysis.

3.5. Installation and Removal of Protective Groups

Protective groups play a key role in multistep synthesis. When the synthetic target is a relatively complex molecule, a sequence of reactions that would be expected to lead to the desired product must be devised. At the present time, syntheses requiring 15–20 steps are common and many that are even longer have been completed. In the planning and execution of such multistep syntheses, an important consideration is the compatibility of the functional groups that are already present with the reaction conditions required for subsequent steps. It is frequently necessary to modify a functional group in order to prevent interference with some reaction in the synthetic sequence. A protective group can be put in place and then subsequently removed in order to prevent an undesired reaction or other adverse influence. For example, alcohols are often protected as trisubstituted silyl ethers and carbonyl groups as acetals. The silyl group masks both the acidity and nucleophilicity of the hydroxy group. An acetal group can prevent both unwanted nucleophilic additions or enolate formation at a carbonyl group.

Three considerations are important in choosing an appropriate protective group: (1) the nature of the group requiring protection; (2) the reaction conditions under which the protective group must be stable; and (3) the conditions that can be tolerated for removal of the protecting group. No universal protective groups exist. The state of the art has been developed to a high level, however, and the many mutually complementary protective groups provide a great degree of flexibility in the design of syntheses of complex molecules.¹⁴⁹ Protective groups play a passive role in synthesis, but each operation of introduction and removal of a protective group adds steps to the synthetic sequence. It is thus desirable to minimize the number of such operations. Fortunately, the methods for protective group installation and removal have been highly developed and the yields are usually excellent.

3.5.1. Hydroxy-Protecting Groups

3.5.1.1. Acetals as Protective Groups. A common requirement in synthesis is that a hydroxy group be masked as a derivative lacking the proton. Examples of this requirement are reactions involving Grignard or other strongly basic organometallic

¹⁴⁹ T. W. Green and P. G. Wuts, *Protective Groups in Organic Synthesis*, 3rd Edition, Wiley, New York, 1999; P. J. Kocienski, *Protective Groups*, Thieme, New York, 2000.

reagents. The acidic proton of a hydroxy group will destroy one equivalent of a strongly basic organometallic reagent and possibly adversely affect the reaction in other ways. In some cases, protection of the hydroxy group also improves the solubility of alcohols in nonpolar solvents. The choice of the most appropriate group is largely dictated by the conditions that can be tolerated in subsequent removal of the protecting group. The tetrahydropyranyl ether (THP) is applicable when mildly acidic hydrolysis is an appropriate group for deprotection.¹⁵⁰ The THP group, like other acetals and ketals, is inert to basic and nucleophilic reagents and is unchanged under such conditions as hydride reduction, organometallic reactions, or base-catalyzed reactions in aqueous solution. It also protects the hydroxy group against oxidation. The THP group is introduced by an acid-catalyzed addition of the alcohol to the vinyl ether moiety in dihydropyran. *p*-Toluenesulfonic acid or its pyridinium salt are frequently used as the catalyst,¹⁵¹ although other catalysts are advantageous in special cases.

The THP group can be removed by dilute aqueous acid. The chemistry involved in both the introduction and deprotection stages is the reversible acid-catalyzed formation and hydrolysis of an acetal (see Part A, Section 7.1).

Various Lewis acids also promote hydrolysis of THP groups. Treatment with five equivalents of LiCl and ten equivalents of H₂O in DMSO removes THP groups in high yield.¹⁵² PdCl₂(CH₃CN)₂ smoothly removes THP groups from primary alcohols.¹⁵³ CuCl₂ is also reported to catalyze hydrolysis of the THP group.¹⁵⁴ These procedures may involve generation of protons by interaction of water with the metal cations.

A disadvantage of the THP group is the fact that a new stereogenic center is produced at C(2) of the tetrahydropyran ring. This presents no difficulties if the alcohol is achiral, since a racemic mixture results. However, if the alcohol is chiral, the reaction gives a mixture of diastereomers, which may complicate purification and/or characterization. One way of avoiding this problem is to use methyl 2-propenyl ether in place of dihydropyran (abbreviated MOP, for methoxypropyl). No new chiral center

is introduced, and this acetal offers the further advantage of being hydrolyzed under somewhat milder conditions than those required for THP ethers.¹⁵⁵

Ethyl vinyl ether is also useful for hydroxy group protection. The resulting derivative (1-ethoxyethyl ether) is abbreviated as the EE group.¹⁵⁶ As with the THP group, the EE group introduces an additional stereogenic center.

The methoxymethyl (MOM) and β -methoxyethoxymethyl (MEM) groups are used to protect alcohols and phenols as formaldehyde acetals. These groups are normally introduced by reaction of an alkali metal salt of the alcohol with methoxymethyl chloride or β -methoxyethoxymethyl chloride.¹⁵⁷

The MOM and MEM groups can be cleaved by pyridinium tosylate in moist organic solvents.¹⁵⁸ An attractive feature of the MEM group is the ease with which it can be removed under nonaqueous conditions. Reagents such as zinc bromide, magnesium bromide, titanium tetrachloride, dimethylboron bromide, or trimethylsilyl iodide permit its removal.¹⁵⁹ The MEM group is cleaved in preference to the MOM or THP groups under these conditions. Conversely, the MEM group is more stable to acidic aqueous hydrolysis than the THP group. These relative reactivity relationships allow the THP and MEM groups to be used in a complementary fashion when two hydroxy groups must be deprotected at different points in a synthetic sequence.

Ref. 160

The methylthiomethyl (MTM) group is a related alcohol-protecting group. There are several methods for introducing the MTM group. Alkylation of an alcoholate by

methylthiomethyl chloride is efficient if catalyzed by iodide ion.¹⁶¹ Alcohols are also converted to MTM ethers by reaction with dimethyl sulfoxide in the presence of acetic acid and acetic anhydride,¹⁶² or with benzoyl peroxide and dimethyl sulfide.¹⁶³ The latter two methods involve the generation of the methylthiomethyl cation by ionization of an acyloxysulfonium ion (Pummerer reaction).

The MTM group is selectively removed under nonacidic conditions in aqueous solutions containing Ag^+ or Hg^{2+} salts. The THP and MOM groups are stable under these conditions.¹⁶¹ The MTM group can also be removed by reaction with methyl iodide, followed by hydrolysis of the resulting sulfonium salt in moist acetone.¹⁶²

Two substituted alkoxymethoxy groups are designed for cleavage involving β -elimination. The 2,2,2-trichloroethoxymethyl groups can be cleaved by reducing agents, including zinc, samarium diiodide, and sodium amalgam.¹⁶⁴ The β -elimination results in the formation of a formaldehyde hemiacetal, which decomposes easily.

The 2-(trimethylsilyl)ethoxymethyl group (SEM) can be removed by various fluoride sources, including TBAF, pyridinium fluoride, and HF.¹⁶⁵ This deprotection involves nucleophilic attack at silicon, which triggers β -elimination.

The SEM group can also be cleaved by MgBr_2 . A noteworthy aspect of this method is that trisubstituted silyl ethers (see below) can survive.

MgBr₂ removal of SEM groups is also useful for deprotection of carboxy groups in N-protected amino acids.

Ref. 167

3.5.1.2. Ethers as Protective Groups. The simple alkyl groups are generally not very useful for protection of alcohols as ethers. Although they can be introduced readily by alkylation, subsequent cleavage requires strongly electrophilic reagents such as boron tribromide (see Section 3.3). The *t*-butyl group is an exception and has found some use as a hydroxy-protecting group. Owing to the stability of the *t*-butyl cation, *t*-butyl ethers can be cleaved under moderately acidic conditions. Trifluoroacetic acid in an inert solvent is frequently used.¹⁶⁸ *t*-Butyl ethers can also be cleaved by acetic anhydride–FeCl₃ in ether.¹⁶⁹ The *t*-butyl group is normally introduced by reaction of the alcohol with isobutylene in the presence of an acid catalyst.^{11,170} Acidic ion exchange resins are effective catalysts.¹⁷¹

The triphenylmethyl (trityl, abbreviated Tr) group is removed under even milder conditions than the *t*-butyl group and is an important hydroxy-protecting group, especially in carbohydrate chemistry.¹⁷² This group is introduced by reaction of the alcohol with triphenylmethyl chloride via an S_N1 substitution. Owing to their steric bulk, triarylmethyl groups are usually introduced only at primary hydroxy groups. Reactions at secondary hydroxy groups can be achieved using stronger organic bases such as DBU.¹⁷³ Hot aqueous acetic acid suffices to remove the trityl group. The ease of removal can be increased by addition of ERG substituents. The *p*-methoxy (PMTr) and *p,p'*-dimethoxy (DMTr) derivatives are used in this way.¹⁷⁴ Trityl groups can also be removed oxidatively using Ce(NH₃)₆(NO₃)₃ (CAN) on silica.¹⁷⁵ This method involves a single-electron oxidation and, as expected, the rate of reaction is DMTr > PMTr > Tr. The DMTr group is especially important in the protection of primary hydroxy groups in nucleotide synthesis (see Section 13.3.2).

The benzyl group can serve as a hydroxy-protecting group if acidic conditions for ether cleavage cannot be tolerated. The benzyl C–O bond is cleaved by catalytic hydrogenolysis,¹⁷⁶ or by electron-transfer reduction using sodium in liquid ammonia or

¹⁷⁶ W. H. Hartung and R. Simonoff, *Org. React.*, **7**, 263 (1953).

aromatic radical anions.¹⁷⁷ Benzyl ethers can also be cleaved using formic acid, cyclohexene, or cyclohexadiene as hydrogen sources in transfer hydrogenolysis catalyzed by platinum or palladium.¹⁷⁸ Several nonreductive methods for cleavage of benzyl ether groups have also been developed. Treatment with *s*-butyllithium, followed by reaction with trimethyl borate and then hydrogen peroxide liberates the alcohol.¹⁷⁹ The lithiated ether forms an alkyl boronate, which is oxidized as discussed in Section 4.5.2.

Lewis acids such as FeCl_3 and SnCl_4 also cleave benzyl ethers.¹⁸⁰

Benzyl groups having 4-methoxy (PMB) or 3,5-dimethoxy (DMB) substituents can be removed oxidatively by dichlorodicyanoquinone (DDQ).¹⁸¹ These reactions presumably proceed through a benzylic cation and the methoxy substituent is necessary to facilitate the oxidation.

These reaction conditions do not affect most of the other common hydroxy-protecting groups and the methoxybenzyl group is therefore useful in synthetic sequences that require selective deprotection of different hydroxy groups. 4-Methoxybenzyl ethers can also be selectively cleaved by dimethylboron bromide.¹⁸²

Benzyl groups are usually introduced by the Williamson reaction (Section 3.2.3). They can also be prepared under nonbasic conditions if necessary. Benzyl alcohols are converted to trichloroacetimidates by reaction with trichloroacetonitrile. These then react with an alcohol to transfer the benzyl group.¹⁸³

Phenyldiazomethane can also be used to introduce benzyl groups.¹⁸⁴

4-Methoxyphenyl (PMP) ethers find occasional use as hydroxy protecting groups. Unlike benzylic groups, they cannot be made directly from the alcohol. Instead, the phenoxy group must be introduced by a nucleophilic substitution.¹⁸⁵ Mitsunobu conditions are frequently used.¹⁸⁶ The PMP group can be cleaved by oxidation with CAN.

Allyl ethers can be removed by conversion to propenyl ethers, followed by acidic hydrolysis of the resulting enol ether.

The isomerization of an allyl ether to a propenyl ether can be achieved either by treatment with potassium *t*-butoxide in dimethyl sulfoxide¹⁸⁷ or by catalysts such as $\text{Rh}(\text{PPh}_3)_3\text{Cl}$ ¹⁸⁸ or $\text{RhH}(\text{PPh}_3)_4$.¹⁸⁹ Heating allyl ethers with Pd-C in acidic methanol can also effect cleavage of allyl ethers.¹⁹⁰ This reaction, too, is believed to involve isomerization to the 1-propenyl ether. Other very mild conditions for allyl group cleavage include Wacker oxidation conditions¹⁹¹ (see Section 8.2.1) and DiBALH with catalytic $\text{NiCl}_2(\text{dppp})$.¹⁹²

3.5.1.3. Silyl Ethers as Protective Groups. Silyl ethers play a very important role as hydroxy-protecting groups.¹⁹³ Alcohols can be easily converted to trimethylsilyl (TMS) ethers by reaction with trimethylsilyl chloride in the presence of an amine or by heating with hexamethyldisilazane. Trimethylsilyl groups are easily removed by hydrolysis or by exposure to fluoride ions. *t*-Butyldimethylsilyl (TBDMS) ethers are also very useful. The increased steric bulk of the TBDMS group improves the stability of the group toward such reactions as hydride reduction and Cr(VI) oxidation. The TBDMS group is normally introduced using a tertiary amine as a catalyst in the reaction of the alcohol with *t*-butyldimethylsilyl chloride or triflate. Cleavage of the TBDMS group is slow under hydrolytic conditions, but anhydrous tetra-*n*-butylammonium fluoride (TBAF),¹⁹⁴ methanolic NH_4F ,¹⁹⁵ aqueous HF,¹⁹⁶ BF_3 ,¹⁹⁷ or SiF_4 ¹⁹⁸ can be used for its removal. Other highly substituted silyl groups, such as dimethyl(1,2,2-trimethylpropyl)silyl¹⁹⁹ and *tris*-isopropylsilyl,²⁰⁰ (TIPS) are even more

sterically hindered than the TBDMS group and can be used when added stability is required. The triphenylsilyl (TPS) and *t*-butyldiphenylsilyl (TBDPS) groups are also used.²⁰¹ The hydrolytic stability of the various silyl protecting groups is in the order TMS < TBDMS < TIPS < TBDPS.²⁰² All the groups are also susceptible to TBAF cleavage, but the TPS and TBDPS groups are cleaved more slowly than the trialkylsilyl groups.²⁰³ Bromine in methanol readily cleaves TBDMS and TBDPS groups.²⁰⁴

3.5.1.4. Esters as Protective Groups. Protection of an alcohol function by esterification sometimes offers advantages over use of acetal or ether groups. Generally, esters are stable under acidic conditions, and they are especially useful in protection during oxidations. Acetates, benzoates, and pivalates, which are the most commonly used derivatives, can be conveniently prepared by reaction of unhindered alcohols with acetic anhydride, benzoyl chloride, or pivaloyl chloride, respectively, in the presence of pyridine or other tertiary amines. 4-Dimethylaminopyridine (DMAP) is often used as a catalyst. The use of *N*-acylimidazolides (see Section 3.4.1) allows the acylation reaction to be carried out in the absence of added base.²⁰⁵ Imidazolides are less reactive than the corresponding acyl chloride and can exhibit a higher degree of selectivity in reactions with a molecule possessing several hydroxy groups.

Hindered hydroxy groups may require special acylation procedures. One approach is to increase the reactivity of the hydroxy group by converting it to an alkoxide ion with strong base (e.g., *n*-BuLi or KH). When this conversion is not feasible, a more reactive acylating reagent is used. Highly reactive acylating agents are generated in situ when carboxylic acids are mixed with trifluoroacetic anhydride. The mixed anhydride exhibits increased reactivity because of the high reactivity of the trifluoroacetate ion as a leaving group.²⁰⁷ Dicyclohexylcarbodiimide is another reagent that serves to activate carboxy groups.

Ester groups can be removed readily by base-catalyzed hydrolysis. When basic hydrolysis is inappropriate, special acyl groups are required. Trichloroethyl carbonate esters, for example, can be reductively removed with zinc.²⁰⁸

Allyl carbonate esters are also useful hydroxy-protecting groups and are introduced using allyl chloroformate. A number of Pd-based catalysts for allylic deprotection have been developed.²⁰⁹ They are based on a catalytic cycle in which Pd⁰ reacts by oxidative addition and activates the allylic bond to nucleophilic substitution. Various nucleophiles are effective, including dimedone,²¹⁰ pentane-2,4-dione,²¹¹ and amines.²¹²

Table 3.1 gives the structure and common abbreviation of some of the most frequently used hydroxy-protecting groups.

3.5.1.5. Protective Groups for Diols. Diols represent a special case in terms of applicable protecting groups. 1,2- and 1,3-diols easily form cyclic acetals with aldehydes and ketones, unless cyclization is precluded by molecular geometry. The isopropylidene derivatives (also called acetonides) formed by reaction with acetone are a common example.

The isopropylidene group can also be introduced by acid-catalyzed exchange with 2,2-dimethoxypropane.²¹³

This acetal protective group is resistant to basic and nucleophilic reagents, but is readily removed by aqueous acid. Formaldehyde, acetaldehyde, and benzaldehyde are also used as the carbonyl component in the formation of cyclic acetals, and they function in the same manner as acetone. A disadvantage in the case of acetaldehyde and benzaldehyde is the possibility of forming a mixture of diastereomers, because of the new stereogenic center at the acetal carbon. Owing to the multiple hydroxy groups present in carbohydrates, the use of cyclic acetal protecting groups is common.

SECTION 3.5
Installation and Removal
of Protective Groups

Cyclic carbonate esters are easily prepared from 1,2- and 1,3-diols. These are commonly prepared by reaction with *N,N'*-carbonyldiimidazole²¹⁴ or by transesterification with diethyl carbonate.

3.5.2. Amino-Protecting Groups

Amines are nucleophilic and easily oxidized. Primary and secondary amino groups are also sufficiently acidic that they are deprotonated by many organometallic reagents. If these types of reactivity are problematic, the amino group must be protected. The

²¹⁴ J. P. Kutney and A. H. Ratcliffe, *Synth. Commun.*, 547 (1975).

most general way of masking nucleophilicity is by acylations, and carbamates are particularly useful. A most effective group for this purpose is the carbobenzyloxy (Cbz) group,²¹⁵ which is introduced by acylation of the amino group using benzyl chloroformate. The amine can be regenerated from a Cbz derivative by hydrogenolysis of the benzyl C–O bond, which is accompanied by spontaneous decarboxylation of the resulting carbamic acid.

In addition to standard catalytic hydrogenolysis, methods for transfer hydrogenolysis using hydrogen donors such as ammonium formate or formic acid with Pd-C catalyst are available.²¹⁶ The Cbz group also can be removed by a combination of a Lewis acid and a nucleophile: for example, boron trifluoride in conjunction with dimethyl sulfide or ethyl sulfide.²¹⁷

The *t*-butoxycarbonyl (*t*Boc) group is another valuable amino-protecting group. The removal in this case is done with an acid such as trifluoroacetic acid or *p*-toluenesulfonic acid.²¹⁸ *t*-Butoxycarbonyl groups are introduced by reaction of amines with *t*-butoxypyrocarbonate or a mixed carbonate-imidate ester known as “BOC-ON.”²¹⁹

Another carbamate protecting group is 2,2,2-trichloroethoxycarbonyl, known as Troc. 2,2,2-Trichloroethylcarbamates can be reductively cleaved by zinc.²²⁰

Allyl carbamates also can serve as amino-protecting groups. The allyloxy group is removed by Pd-catalyzed reduction or nucleophilic substitution. These reactions involve formation of the carbamic acid by oxidative addition to the palladium. The allyl-palladium species is reductively cleaved by stannanes,²²¹ phenylsilane,²²² formic acid,²²³ and NaBH₄,²²⁴ which convert the allyl group to propene. Reagents

used for nucleophilic cleavage include *N,N'*-dimethylbarbituric acid,²²⁵ and silylating agents, including TMS-N₃/NH₄F,²²⁶ TMSN(Me)₂,²²⁷ and TMSN(CH₃)COCF₃.²¹⁹ The silylated nucleophiles trap the deallylated product prior to hydrolytic workup.

Allyl groups attached directly to amine or amide nitrogen can be removed by isomerization and hydrolysis.²²⁸ These reactions are analogous to those used to cleave allylic ethers (see p. 266). Catalysts that have been found to be effective include Wilkinson's catalyst,²²⁹ other rhodium catalysts,²³⁰ and iron pentacarbonyl.⁴⁵ Treatment of *N*-allyl amines with Pd(PPh₃)₄ and *N,N'*-dimethylbarbituric acid also cleaves the allyl group.²³¹

Sometimes it is useful to be able to remove a protecting group by photolysis. 2-Nitrobenzyl carbamates meet this requirement. The photoexcited nitro group abstracts a hydrogen from the benzylic position, which is then converted to a α -hydroxybenzyl carbamate that readily hydrolyzes.²³²

N-Benzyl groups can be removed from tertiary amines by reaction with chloroformates. This can be a useful method for protective group manipulation if the resulting carbamate is also easily cleaved. A particularly effective reagent is α -chloroethyl chloroformate, which can be removed by subsequent solvolysis,²³³ and it has been used to remove methyl and ethyl groups. These reactions are related to ether cleavage by acylation reagents (see Section 3.3).

Simple amides are satisfactory protecting groups only if the rest of the molecule can resist the vigorous acidic or alkaline hydrolysis necessary for removal. For this

reason, only amides that can be removed under mild conditions are useful as amino-protecting groups. Phthalimides, which are used to protect primary amino groups, can be cleaved by treatment with hydrazine, as in the Gabriel synthesis of amines (see Section 3.2.4). This reaction proceeds by initial nucleophilic addition at an imide carbonyl, followed by an intramolecular acyl transfer.

A similar sequence that takes place under milder conditions uses 4-nitrophthalimides as the protecting group and *N*-methylhydrazine for deprotection.²³⁴ Reduction by NaBH_4 in aqueous ethanol is an alternative method for deprotection of phthalimides. This reaction involves formation of an *o*-hydroxybenzamide in the reduction step. Intramolecular displacement of the amino group follows.²³⁵

Owing to the strong EWG effect of the trifluoromethyl group, trifluoroacetamides are subject to hydrolysis under mild conditions. This has permitted trifluoroacetyl groups to be used as amino-protecting groups in some situations. For example, the amino group was protected by trifluoroacetylation during BBr_3 demethylation of **2**.

Ref. 236

Amides can also be deacylated by partial reduction. If the reduction proceeds only to the carbinolamine stage, hydrolysis can liberate the deprotected amine. Trichloroacetamides are readily cleaved by sodium borohydride in alcohols by this mechanism.²³⁷ Benzamides, and probably other simple amides, can be removed by careful partial reduction with diisobutylaluminum hydride (see Section 5.3.1.1).²³⁸

The 4-pentenoyl group is easily removed from amides by I_2 and can be used as a protecting group. The mechanism of cleavage involves iodocyclization and hydrolysis of the resulting iminolactone (see Section 4.2.1).²³⁹

Sulfonamides are very difficult to hydrolyze. However, a photoactivated reductive method for desulfonation has been developed.²⁴⁰ Sodium borohydride is used in conjunction with 1,2- or 1,4-dimethoxybenzene or 1,5-dimethoxynaphthalene. The photoexcited aromatic serves as an electron donor toward the sulfonyl group, which then fragments to give the deprotected amine. The NaBH_4 reduces the radical cation and the sulfonyl radical.

Table 3.2 summarizes the common amine-protecting groups. Reagents that permit protection of primary amino groups as cyclic *bis*-silyl derivatives have been developed. Anilines, for example, can be converted to disilazolidines.²⁴¹ These groups are stable to a number of reaction conditions, including generation and reaction of organometallic reagents.²⁴² They are readily removed by hydrolysis.

Amide nitrogens can be protected by 4-methoxy or 2,4-dimethoxyphenyl groups. The protecting group can be removed by oxidation with ceric ammonium nitrate.²⁴³ 2,4-Dimethoxybenzyl groups can be removed using anhydrous trifluoroacetic acid.²⁴⁴

3.5.3. Carbonyl-Protecting Groups

Conversion to acetals is a very general method for protecting aldehydes and ketones against nucleophilic addition or reduction.²⁴⁵ Ethylene glycol, which gives a cyclic dioxolane derivative, is frequently employed for this purpose. The dioxolanes are usually prepared by heating a carbonyl compound with ethylene glycol in the presence of an acid catalyst, with provision for azeotropic removal of water.

²⁴⁵ A. R. Hajipour, S. Khoei, and A. E. Ruoho, *Org. Prep. Proced. Int.*, **35**, 527 (2003).

Scandium triflate is also an effective catalyst for dioxolane formation.²⁴⁶

Dimethyl or diethyl acetals can be prepared by acid-catalyzed exchange with an acetal such as 2,2-dimethoxypropane or an orthoester.²⁴⁷

Acetals can be prepared under very mild conditions by reaction of the carbonyl compound with a trimethylsilyl ether, using trimethylsilyl trifluoromethylsulfonate as the catalyst.²⁴⁸

The carbonyl group can be deprotected by acid-catalyzed hydrolysis by the general mechanism for acetal hydrolysis (see Part A, Section 7.1). A number of Lewis acids have also been used to remove acetal protective groups. Hydrolysis is promoted by LiBF_4 in acetonitrile.²⁴⁹ Bismuth triflate promotes hydrolysis of dimethoxy, diethoxy, and dioxolane acetals.²⁵⁰ The dimethyl and diethyl acetals are cleaved by 0.1–1.0 mol % of catalyst in aqueous THF at room temperature, whereas dioxolanes require reflux. Bismuth nitrate also catalyzes acetal hydrolysis.²⁵¹

If the carbonyl group must be regenerated under nonhydrolytic conditions, β -halo alcohols such as 3-bromopropane-1,2-diol or 2,2,2-trichloroethanol can be used for acetal formation. These groups can be removed by reduction with zinc, which leads to β -elimination.

Ref. 253

Another carbonyl-protecting group is the 1,3-oxathiolane derivative, which can be prepared by reaction with mercaptoethanol in the presence of a number of Lewis acids including BF_3 ²⁵⁴ and $\text{In}(\text{OTf})_3$ ²⁵⁵ or by heating with an acid catalyst with azeotropic removal of water.²⁵⁶ The 1,3-oxathiolanes are particularly useful when nonacidic conditions are required for deprotection. The 1,3-oxathiolane group can be removed by treatment with Raney nickel in alcohol, even under slightly alkaline conditions.²⁵⁷ Deprotection can also be accomplished by treating with a mild halogenating agent, such as NBS,²⁵⁸ tetrabutylammonium tribromide,²⁵⁹ or chloramine-T.²⁶⁰ These reagents oxidize the sulfur to a halosulfonium salt and activate the ring to hydrolytic cleavage.

Dithioketals, especially the cyclic dithiolanes and dithianes, are also useful carbonyl-protecting groups.²⁶¹ These can be formed from the corresponding dithiols by Lewis acid-catalyzed reactions. The catalysts that are used include BF_3 , $\text{Mg}(\text{O}_3\text{SCF}_3)_2$, $\text{Zn}(\text{O}_3\text{SCF}_3)_2$, and LaCl_3 .²⁶² *S*-Trimethylsilyl ethers of thiols and dithiols also react with ketones to form dithioketals.²⁶³ *Bis*-trimethylsilyl sulfate in the presence of silica also promotes formation of dithiolanes.²⁶⁴ Di-*n*-butylstannyldithiolates also serve as sources of dithiolanes and dithianes. These reactions are catalyzed by di-*n*-butylstannyl ditriflate.²⁶⁵

The regeneration of carbonyl compounds from dithioacetals and dithiolanes is often done with reagents that oxidize or otherwise activate the sulfur as a leaving

group and facilitate hydrolysis. Among the reagents that have been found effective are nitrous acid, *t*-butyl hypochlorite, NaClO_2 , $\text{PhI}(\text{O}_2\text{CCF}_3)_2$, DDQ, SbCl_5 , and cupric salts.²⁶⁶

3.5.4. Carboxylic Acid–Protecting Groups

If only the O–H, as opposed to the carbonyl, of a carboxyl group has to be masked, it can be readily accomplished by esterification. Alkaline hydrolysis is the usual way for regenerating the acid. *t*-Butyl esters, which are readily cleaved by acid, can be used if alkaline conditions must be avoided. 2,2,2-Trichloroethyl esters, which can be reductively cleaved with zinc, are another possibility.²⁶⁷ Some esters can be cleaved by treatment with anhydrous TBAF. These reactions proceed best for esters of relatively acidic alcohols, such as 4-nitrobenzyl, 2,2,2-trichloroethyl, and cyanoethyl.²⁶⁸

The more difficult problem of protecting the carbonyl group can be accomplished by conversion to an oxazoline derivative. One example is the 4,4-dimethyl derivative, which can be prepared from the acid by reaction with 2-amino-2-methylpropanol or with 2,2-dimethylaziridine.²⁶⁹

The heterocyclic derivative successfully protects the acid from attack by Grignard or hydride-transfer reagents. The carboxylic acid group can be regenerated by acidic hydrolysis or converted to an ester by acid-catalyzed reaction with the appropriate alcohol.

Carboxylic acids can also be protected as orthoesters. Orthoesters derived from simple alcohols are very easily hydrolyzed, and the 4-methyl-2,6,7-trioxabicyclo[2.2.2]octane structure is a more useful orthoester protecting group. These

derivatives can be prepared by exchange with other orthoesters,²⁷⁰ by reaction with iminoethers,²⁷¹ or by rearrangement of the ester derived from 3-hydroxymethyl-3-methyloxetane.²⁷²

The latter method is improved by use of the 2,2-dimethyl derivative.²⁷³ The rearrangement is faster and the stability of the orthoester to hydrolysis is better. Isotopic labeling showed that the rearrangement occurs by ionization at the tertiary position.

Lactones can be protected as dithiolane derivatives using a method that is analogous to ketone protection. The required reagent is readily prepared from trimethylaluminum and ethanedithiol.

Ref. 274

Acyclic esters react with this reagent to give ketene dithio acetals.

In general, the methods for protection and deprotection of carboxylic acids and esters are not as convenient as for alcohols, aldehydes, and ketones. It is therefore common to carry potential carboxylic acids through synthetic schemes in the form of protected primary alcohols or aldehydes. The carboxylic acid can then be formed at a late stage in the synthesis by an appropriate oxidation. This strategy allows one to utilize the wider variety of alcohol and aldehyde protective groups indirectly for carboxylic acid protection.

(References for these problems will be found on page 1275.)

3.1. Give the products that would be expected to be formed under the specified reaction conditions. Be sure to specify all aspects of the stereochemistry.

3.2. When (*R*)-(-)-5-hexen-2-ol was treated with Ph_3P in refluxing, CCl_4 , (+)-5-chloro-1-hexene was obtained. Conversion of (*R*)-(-)-5-hexen-2-ol to its 4-bromobenzenesulfonate ester and subsequent reaction with LiCl gave (+)-5-chloro-1-hexene. Reaction of (*S*)-(+)-5-hexen-2-ol with PCl_5 in ether gave (-)-5-chloro-1-hexene.

- Write chemical equations for each of these reactions and specify whether each occurs with net retention or inversion of configuration.
- What is the sign of rotation of (*R*)-5-chloro-1-hexene?

3.3. A careful investigation of the extent of isomeric products formed by reaction of several alcohols with thionyl chloride has been reported. The product compositions for several of the alcohols are given below. Identify the structural features that promote isomerization and show how each of the rearranged products is formed.

$\text{ROH} \xrightarrow[100^\circ\text{C}]{\text{SOCl}_2} \text{RCl}$		
R	Percent unrearranged RCl	Structure and amount of rearranged RCl
$\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}_2-$	100	
$(\text{CH}_3)_2\text{CHCH}_2-$	99.7	$(\text{CH}_3)_2\text{CHCH}_3$
$(\text{CH}_3)_2\text{CHCH}_2\text{CH}_2-$	100	Cl 0.3%
$\text{CH}_3\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}_2-$	78	$\text{CH}_3\text{CH}(\text{CH}_3)\text{CH}_2\text{CH}_2\text{CH}_3$, $\text{CH}_3\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}_2\text{CH}_3$, $\text{CH}_3\text{CH}_2\text{C}(\text{CH}_3)_2$
$(\text{CH}_3)_3\text{CCH}_2-$	2	Cl 1%, Cl 11%, Cl 10%
$\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}_3$	98	$\text{CH}_3\text{CH}_2\text{C}(\text{CH}_3)_2$
$\text{CH}_3\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}_2\text{CH}_3$	90	Cl 98%, $\text{CH}_3\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}_2\text{CH}_3$
$(\text{CH}_3)_2\text{CHCH}(\text{CH}_3)\text{CH}_3$	5	Cl 2%, $\text{CH}_3\text{CH}_2\text{CH}_2\text{CH}(\text{CH}_3)\text{CH}_3$

		Cl 95%

3.4. Give a reaction mechanism that would explain the following observations and reactions.

- a. Kinetic measurements reveal that solvolytic displacement of sulfonate is about 5×10^5 faster for **4B** than for **4A**.

b.

c.

d.

e.

f.

g.

h. Both **4C** and **4D** gave the same product when subjected to Mitsunobu conditions with phenol as the nucleophile.

3.5. Substances such as carbohydrates and amino acids as well as other small molecules available from natural sources are valuable starting materials in enantiospecific syntheses. Suggest reagents that could effect the following transformations, taking particular care to ensure that the product will be enantiomerically pure.

(a)

(b)

(c)

3.6. Indicate conditions that would be appropriate for the following transformations involving introduction or removal of protective groups:

3.7. Suggest reagents and approximate reaction conditions that would effect the following conversions. Note any special features of the reactant that should be taken into account in choosing a reagent system.

3.8. Provide a mechanistic interpretation of the following reactions and observations.

- a. Show the mechanism for inversion of a hydroxyl site under the Mitsunobu conditions, as illustrated by the reaction of cholesterol.

- b. Triphenylphosphine oxide reacts with trifluoromethylsulfonic anhydride to give an ionic substance having the composition of a 1:1 adduct. When this substance is added to a solution containing a carboxylic acid, followed by addition of an amine, amides are formed in good yield. Similarly, esters are formed on reaction with alcohols. What is the structure of the adduct and how does it activate the carboxylic acids to nucleophilic substitution?
- c. Sulfonate esters having quaternary nitrogen substituents, such as **8A** and **8B**, show high reactivity toward nucleophilic substitution. Sulfonates **8A** are comparable in reactivity to 2,2,2-trifluoroethylsulfonate in homogeneous solution and are even more reactive in two-phase solvent mixtures.

- d. Alcohols react with hexachloroacetone in the presence of DMF to give alkyl trichloroacetates in good yield. Primary alcohols react faster than secondary alcohols, but tertiary alcohols are unreactive under these conditions.
- e. The β -hydroxy- α -amino acids serine and threonine can be converted to their respective *bis*-*O*-*t*-butyl derivatives on reaction with isobutene and H_2SO_4 . Subsequent treatment with one equivalent of trimethylsilyl triflate and then water cleaves the ester group, but not the ether group. What is the basis for this selectivity?

- f. 2'-Deoxyadenosine can be cleanly converted to its 5'-chloro analog by reaction with 1.5 equivalent of SOCl_2 in HMPA. The reaction proceeds through an intermediate of composition $\text{C}_{20}\text{H}_{22}\text{N}_{10}\text{Cl}_2\text{O}_5\text{S}$, which is converted to the product on exposure to aqueous ammonia. With larger amounts of SOCl_2 , the 3'/5'-dichloro derivative is formed.

- 3.9. Short synthetic sequences have been used to obtain the material on the left from the starting material on the right. Suggest an appropriate method. No more than three steps should be required.

- 3.10. Amino acids can be converted to epoxides of high enantiomeric purity by the reaction sequence below. Analyze the stereochemistry of each step of the reaction sequence.

3.11. Indicate the product to be expected under the following reaction conditions:

- 3.12. A reagent that can introduce benzyloxycarbonyl protecting groups on amino groups in nucleosides is prepared by allowing benzyl chloroformate to react first with imidazole and then with trimethyloxonium tetrafluoroborate. What is the structure of the resulting reagent (a salt) and why is it an especially reactive acylating agent?
- 3.13. Triphenylphosphine reacts with peroxides to give intermediates that are related to those formed in the Mitsunobu reaction. The following reactions are examples:

What properties of the intermediates in the Mitsunobu reaction are suggested by these reactions?

- 3.14. The scope of the reaction of $\text{Ph}_3\text{P-Cl}_3\text{CCOCCl}_3$ with allylic alcohols has been studied. Primary and some secondary alcohols, such as **14A** and **14B**, give good

yields of unrearranged allylic chlorides. The reaction also exhibits retention of *E,Z*-configuration at the allylic double bonds (**14C** and **14D**). Certain other alcohols, such as **14E** and **14F**, give more complex mixtures. What structural features determine how cleanly the alcohol is converted to chloride? How are these structural features related to the mechanism of the reaction?

- 3.15. In each of the synthetic transformations shown, the reagents are appropriate for the desired transformation but the reaction would not succeed as written. Suggest a protective group strategy that would permit each transformation to be carried out to give the desired product.

- 3.16. Two heterocyclic ring systems that have found some use in the formation of amides under mild conditions are *N*-alkyl-5-arylisoxazolium salts (**16A**) and *N*-acyloxy-2-alkoxydihydroquinolines (**16B**).

Typical reaction conditions for these reagents are shown below. Propose mechanisms by which these heterocyclic molecules can function to activate carboxy groups under these conditions.

- 3.17. Either because of potential interference with other functional groups present in the molecule or because of special structural features, the following reactions require careful selection of reagents and reaction conditions. Identify the special requirements in each reactant and suggest appropriate reagents and reaction conditions for each transformation.

- 3.18. The preparation of nucleosides by reaction between carbohydrates and heterocyclic bases is fundamental to the study of the important biological activity

of these substances. Several methods exist for forming the nucleoside bonds. Application of 2-chloro-3-ethylbenzoxazolium chloride to this reaction was investigated using 2,3,4,6-tetra-*O*-acetyl- β -D-glucopyranose. Good yields were observed and the reaction was stereospecific for the β -nucleoside. Suggest a mechanism to explain the retention of configuration.

- 3.19. A route to α -glycosides involves treatment of a 2,3,4,6-tetra-*O*-benzyl- α -D-glucopyranosyl bromide with an alcohol, tetraethylammonium bromide, and diisopropylethylamine in CH_2Cl_2 . Explain the stereoselectivity of this reaction.

- 3.20. Write mechanisms for formation of 2-pyridylthio esters by the following methods:

- 3.21. The ionophoric antibiotic nonactin is a 32-membered macrocycle that contains two units of (–)-nonactic acid and two units of (+)-nonactic acid in an alternating sequence.

- a. Assuming that you have access to both (+)- and (–)-nonactic acid, devise a strategy and protecting group sequence that could provide the natural macro-molecule in high stereochemical purity.

- b. Suppose you had access to (+)-nonactic acid and the C(8) epimer of (–)-nonactic acid, how could you obtain nonactin?

Nonactin

(+)–nonactic acid

(–)-nonactic acid

- 3.22. Because they are readily available from natural sources in enantiomerically pure form, carbohydrates are very useful starting materials for the synthesis of other enantiomerically pure substances. However, the high number of similar functional groups present in the carbohydrates requires versatile techniques for protection and deprotection. Show how appropriate manipulation of protecting groups and other selective reactions could be employed to effect the following transformations.

Electrophilic Additions to Carbon-Carbon Multiple Bonds

Introduction

Addition of electrophilic reagents is one of the most general and useful reactions of alkenes and alkynes. This chapter focuses on reactions that proceed through polar intermediates or transition structures. We discuss the fundamental mechanistic characteristics of this class of reactions in Chapter 5 of Part A, including proton-catalyzed additions of water and alcohols and the addition of hydrogen halides. Other electrophilic reagents that we consider there are the halogens and positive halogen compounds, electrophilic sulfur and selenium reagents, and mercuric salts. Hydroboration is another important type of electrophilic addition to alkenes. In the present chapter, we emphasize synthetic application of these reactions. For the most part, electrophilic additions are used to introduce functionality at double and triple bonds. When the nucleophile addition step is intramolecular, a new heterocyclic ring is formed, and this is a very useful synthetic method.

Carbonyl compounds can react with electrophiles via their enol isomers or equivalents, and these reactions result in α -substitution.

Several other types of addition reactions of alkenes are also of importance and these are discussed elsewhere. Nucleophilic additions to electrophilic alkenes are covered in Section 2.6 and cycloadditions involving concerted mechanisms are encountered in Sections 6.1 to 6.3. Free radical addition reactions are considered in Chapter 11.

4.1. Electrophilic Addition to Alkenes

4.1.1. Addition of Hydrogen Halides

Hydrogen chloride and hydrogen bromide react with alkenes to give addition products. In early work, it was observed that addition usually takes place to give the product with the halogen atom attached to the more-substituted carbon of the double bond. This behavior is sufficiently general that the name *Markovnikov's rule* was given to the statement describing this mode of addition. The term *regioselective* is used to describe addition reactions that proceed selectively in one direction with unsymmetrical alkenes.¹ A rudimentary picture of the reaction mechanism indicates the basis of Markovnikov's rule. The addition involves either protonation or a partial transfer of a proton to the double bond. The relative stability of the two possible carbocations from an unsymmetrical alkene favors formation of the more-substituted intermediate. Addition is completed when the carbocation reacts with a halide anion.

Markovnikov's rule describes a specific case of regioselectivity that is based on the stabilizing effect of alkyl and aryl substituents on carbocations.

A more complete discussion of the mechanism of addition of hydrogen halides to alkenes is given in Chapter 6 of Part A. In particular, the question of whether or not discrete carbocations are involved is considered there. Even when a carbocation is not involved, the regioselectivity of electrophilic addition is the result of attack of the electrophile at the more *electron-rich* carbon of the double bond. Alkyl substituents increase the electron density of the terminal carbon by hyperconjugation (see Part A, Section 1.1.8).

Terminal and disubstituted internal alkenes react rather slowly with HCl in nonpolar solvents. The rate is greatly accelerated in the presence of silica or alumina in noncoordinating solvents such as dichloromethane or chloroform. Preparatively convenient conditions have been developed in which HCl is generated in situ from SOCl_2 or $(\text{ClCO})_2$.² These heterogeneous reaction systems also give a Markovnikov orientation.

¹ A. Hassner, *J. Org. Chem.*, **33**, 2684 (1968).

² P. J. Kropp, K. A. Daus, M. W. Tubergen, K. D. Kepler, V. P. Wilson, S. L. Craig, M. M. Baillargeon, and G. W. Breton, *J. Am. Chem. Soc.*, **115**, 3071 (1993).

The mechanism is thought to involve an interaction of the silica or alumina surface with HCl that facilitates proton transfer.

Another convenient procedure for hydrochlorination involves adding trimethylsilyl chloride to a mixture of an alkene and water. Good yields of HCl addition products (Markovnikov orientation) are formed.³ These conditions presumably involve generation of HCl by hydrolysis of the silyl chloride, but it is uncertain if the silicon plays any further role in the reaction.

In nucleophilic solvents, products that arise from reaction of the solvent with the cationic intermediate may be formed. For example, reaction of cyclohexene with hydrogen bromide in acetic acid gives cyclohexyl acetate as well as cyclohexyl bromide. This occurs because acetic acid acts as a nucleophile in competition with the bromide ion.

When carbocations are involved as intermediates, carbon skeleton rearrangement can occur during electrophilic addition reactions. Reaction of *t*-butylethylene with hydrogen chloride in acetic acid gives both rearranged and unrearranged chloride.⁵

The stereochemistry of addition of hydrogen halides to alkenes depends on the structure of the alkene and also on the reaction conditions. Addition of hydrogen bromide to cyclohexene and to *E*- and *Z*-2-butene is *anti*.⁶ The addition of hydrogen chloride to 1-methylcyclopentene is entirely *anti* when carried out at 25° C in nitromethane.⁷

1,2-Dimethylcyclohexene is an example of an alkene for which the stereochemistry of hydrogen chloride addition is dependent on the solvent and temperature. At -78°C in dichloromethane, 88% of the product is the result of *syn* addition, whereas at 0°C in ether, 95% of the product results from *anti* addition.⁸ *Syn* addition is particularly common with alkenes having an aryl substituent. Table 4.1 lists several alkenes for which the stereochemistry of addition of hydrogen chloride or hydrogen bromide has been studied.

The stereochemistry of addition depends on the details of the mechanism. The addition can proceed through an ion pair intermediate formed by an initial protonation step. Most alkenes, however, react via a complex that involves the alkene, hydrogen halide, and a third species that delivers the nucleophilic halide. This termolecular mechanism is generally pictured as a nucleophilic attack on an alkene-hydrogen halide complex. This mechanism bypasses a discrete carbocation and exhibits a preference for *anti* addition.

The major factor in determining which mechanism is followed is the stability of the carbocation intermediate. Alkenes that can give rise to a particularly stable carbocation

Table 4.1. Stereochemistry of Addition of Hydrogen Halides to Alkenes

Alkene	Hydrogen halide	Stereochemistry
1,2-Dimethylcyclohexene ^a	HBr	<i>anti</i>
1,2-Dimethylcyclohexene ^a	HCl	Solvent and temperature dependent
Cyclohexene ^b	HBr	<i>anti</i>

are likely to react via the ion pair mechanism, which is not necessarily stereospecific, as the carbocation intermediate permits loss of stereochemistry relative to the reactant alkene. It might be expected that the ion pair mechanism would lead to a preference for *syn* addition, since at the instant of formation of the ion pair, the halide is on the same side of the alkene as the proton being added. Rapid collapse of the ion pair intermediate would lead to *syn* addition. If the lifetime of the ion pair is longer and the ion pair dissociates, a mixture of *syn* and *anti* addition products can be formed. The termolecular mechanism is expected to give *anti* addition because the nucleophilic attack occurs on the opposite side of the double bond from proton addition. Further discussion of the structural features that affect the competition between the two possible mechanisms can be found in Section 6.1 of Part A.

4.1.2. Hydration and Other Acid-Catalyzed Additions of Oxygen Nucleophiles

Oxygen nucleophiles can be added to double bonds under strongly acidic conditions. A fundamental example is the hydration of alkenes in acidic aqueous solution.

Addition of a proton occurs to give the more-substituted carbocation, so addition is regioselective and in accord with Markovnikov's rule. A more detailed discussion of the reaction mechanism is given in Section 6.2 of Part A. Owing to the strongly acidic and rather vigorous conditions required to effect hydration of most alkenes, these conditions are applicable only to molecules that have no acid-sensitive functional groups. The reaction is occasionally applied to the synthesis of tertiary alcohols.

Ref. 9

Moreover, because of the involvement of cationic intermediates, rearrangements can occur in systems in which a more stable cation can result by aryl, alkyl, or hydrogen migration. *Oxymercuration-reduction*, a much milder and more general procedure for alkene hydration, is discussed in the next section.

Addition of nucleophilic solvents such as alcohols and carboxylic acids can be effected by using strong acids as catalysts.¹⁰

Trifluoroacetic acid (TFA) is strong enough to react with alkenes under relatively mild conditions.¹¹ The addition is regioselective in the direction predicted by Markovnikov's rule.

Ring strain enhances alkene reactivity. Norbornene, for example, undergoes rapid addition of TFA at 0°C.¹²

4.1.3. Oxymercuration-Reduction

The addition reactions discussed in Sections 4.1.1 and 4.1.2 are initiated by the interaction of a proton with the alkene. Electron density is drawn toward the proton and this causes nucleophilic attack on the double bond. The role of the electrophile can also be played by metal cations, and the mercuric ion is the electrophile in several synthetically valuable procedures.¹³ The most commonly used reagent is mercuric acetate, but the trifluoroacetate, trifluoromethanesulfonate, or nitrate salts are more reactive and preferable in some applications. A general mechanism depicts a *mercurinium ion* as an intermediate.¹⁴ Such species can be detected by physical measurements when alkenes react with mercuric ions in nonnucleophilic solvents.¹⁵ The cation may be predominantly bridged or open, depending on the structure of the particular alkene. The addition is completed by attack of a nucleophile at the more-substituted carbon. The nucleophilic capture is usually the rate- and product-controlling step.^{13, 16}

The nucleophiles that are used for synthetic purposes include water, alcohols, carboxylate ions, hydroperoxides, amines, and nitriles. After the addition step is complete, the mercury is usually reductively removed by sodium borohydride, the net result being the addition of hydrogen and the nucleophile to the alkene. The regioselectivity is excellent and is in the same sense as is observed for proton-initiated additions.¹⁷

The reductive replacement of mercury using sodium borohydride is a free radical chain reaction involving a mercuric hydride intermediate.¹⁸

The evidence for the free radical mechanism includes the fact that the course of the reaction can be diverted by oxygen, an efficient radical scavenger. In the presence of oxygen, the mercury is replaced by a hydroxy group. Also consistent with a free radical intermediate is the formation of cyclic products when 5-hexenylmercury compounds are reduced with sodium borohydride.¹⁹ This cyclization reaction is highly characteristic of reactions involving 5-hexenyl radicals (see Part A, Section 11.2.3.3). In the presence of oxygen, no cyclic product is formed, indicating that O₂ traps the radical faster than cyclization occurs.

Tri-*n*-butyltin hydride can also be used for reductive demercuration.²⁰ An alternative reagent for demercuration is sodium amalgam in a protic solvent. Here the evidence is that free radicals are not involved and the mercury is replaced with retention of configuration.²¹

The stereochemistry of oxymercuration has been examined in a number of systems. Conformationally biased cyclic alkenes such as 4-*t*-butylcyclohexene and 4-*t*-butyl-1-methycyclohexene give exclusively the product of *anti* addition, which is consistent with a mercurinium ion intermediate.^{17,22}

Norbornene, in contrast reacts by *syn* addition.²³ This is believed to occur by internal transfer of the nucleophile.

The reactivity of different alkenes toward mercuration spans a considerable range and is governed by a combination of steric and electronic factors.²⁴ Terminal double bonds are more reactive than internal ones. Disubstituted terminal alkenes, however, are more reactive than monosubstituted cases, as would be expected for electrophilic attack. (See Part A, Table 5.6 for comparative rate data.) The differences in relative reactivities are large enough that selectivity can be achieved with certain dienes.

Ref. 24

Diastereoselectivity has been observed in oxymercuration of alkenes having nearby oxygen substituents. Terminal allylic alcohols show a preference for formation of the *anti* 2,3-diols.

This result can be explained in terms of a steric preference for conformation **A** over **B**. The approach of the mercuric ion is directed by the hydroxy group. The selectivity increases with the size of the substituent R.²⁵

The directive effect of allylic silyoxy groups has also been examined. The reactions are completely regioselective for 1,3-oxygen substitution. The reaction of

Z-isomers of 2-pentenloxy ethers show modest stereoselectivity, but the *E*-ethers show no stereoselectivity.²⁶ Trisubstituted allylic TBDPS ethers show good stereoselectivity.²⁷

These results are consistent with a directive effect by the silyloxy substituent through the sterically favored conformation of the reactant.

With acetoxy derivatives, the 2,3-*syn* isomer is preferred as a result of direct nucleophilic participation by the carbonyl oxygen.

Polar substituents can exert a directing effect. Cyclohexenol, for example, gives high regioselectivity but low stereoselectivity.²⁸ This indicates that some factor other than hydroxy coordination is involved.

A computational study of remote directing effects was undertaken in substituted norbornenes.²⁹ It was concluded that polar effects of EWGs favors mercuriation at the

carbon that is closer to the substituent, which is attributed to a favorable polar effect that stabilizes the negative charge on the mercurated carbon.

Visual models, additional information and exercises on Oxymercuration can be found in the Digital Resource available at: Springer.com/carey-sundberg.

Scheme 4.1 includes examples of oxymercuration reactions. Entries 1 and 2 illustrate the Markovnikov orientation under typical reaction conditions. The high *exo* selectivity in Entry 3 is consistent with steric approach control on a weakly bridged (or open) mercurinium ion. There is no rearrangement, indicating that the intermediate is a localized cation.

Entries 4 and 5 involve formation of ethers using alcohols as solvents, whereas the reaction in Entry 6 forms an amide in acetonitrile. Entries 7 and 8 show use of other nucleophiles to capture the mercurinium ion.

4.1.4. Addition of Halogens to Alkenes

The addition of chlorine or bromine to an alkene is a very general reaction. Section 6.3 of Part A provides a discussion of the reaction mechanism. Bromination of simple alkenes is extremely fast. Some specific rate data are tabulated and discussed in Section 6.3 of Part A. As halogenation involves electrophilic attack, substituents on the double bond that increase electron density increase the rate of reaction, whereas EWG substituents have the opposite effect. Considerable insight into the mechanism of halogen addition has come from studies of the stereochemistry of the reaction. Most simple alkenes add bromine in a stereospecific manner, giving the product of *anti* addition. Among the alkenes that give *anti* addition products are *Z*-2-butene, *E*-2-butene, maleic and fumaric acid, and a number of cycloalkenes.³⁰ Cyclic, positively charged bromonium ion intermediates provide an explanation for the observed *anti* stereospecificity.

The bridging by bromine prevents rotation about the remaining bond and back-side nucleophilic opening of the bromonium ion by bromide ion leads to the observed *anti* addition. Direct evidence for the existence of bromonium ions has been obtained from NMR measurements.³¹ A bromonium ion salt (with Br_3^- as the counterion) has been isolated from the reaction of bromine with the very hindered alkene adamantylideneadamantane.³²

31. G. A. Olah, J. M. Bollinger, and J. Brinich, *J. Am. Chem. Soc.*, **90**, 2587 (1968); G. A. Olah, P. Schilling, P. W. Westerman, and H. C. Lin, *J. Am. Chem. Soc.*, **96**, 3581 (1974).

32. J. Strating, J. H. Wierenga, and H. Wynberg, *J. Chem. Soc., Chem. Commun.*, 907 (1969).

A substantial amount of *syn* addition is observed for *Z*-1-phenylpropene (27–80% *syn* addition), *E*-1-phenylpropene (17–29% *syn* addition), and *cis*-stilbene (up to 90% *syn* addition in polar solvents).

Ref. 30

A common feature of the compounds that give extensive *syn* addition is the presence of a phenyl substituent on the double bond. The presence of a phenyl substituent diminishes the strength of bromine bridging by stabilizing the cationic center. A weakly bridged structure in equilibrium with an open benzylic cation can account for the loss in stereospecificity.

The diminished stereospecificity is similar to that noted for hydrogen halide addition to phenyl-substituted alkenes.

Although chlorination of aliphatic alkenes usually gives *anti* addition, *syn* addition is often dominant for phenyl-substituted alkenes.³³

These results, too, reflect a difference in the extent of bridging in the intermediates. With unconjugated alkenes, there is strong bridging and high *anti* stereospecificity. Phenyl substitution leads to cationic character at the benzylic site, and there is more *syn* addition. Because of its smaller size and lesser polarizability, chlorine is not as effective as bromine in bridging for any particular alkene. Bromination therefore generally gives a higher degree of *anti* addition than chlorination, all other factors being the same.³⁴

of the bromide ion as low as possible. One method for accomplishing this is to use *N*-bromosuccinimide (NBS) as the brominating reagent.^{38,39} High yields of bromohydrins are obtained by using NBS in aqueous DMSO. The reaction is a stereospecific *anti* addition. As in bromination, a bromonium ion intermediate can explain the *anti* stereospecificity. It has been shown that the reactions in DMSO involve nucleophilic attack by the sulfoxide oxygen. The resulting alkoxy-sulfonium ion intermediate reacts with water to give the bromohydrin.

In accord with the Markovnikov rule, the hydroxy group is introduced at the carbon best able to support positive charge.

Ref. 40

Ref. 41

The participation of sulfoxo groups can be used to control the stereochemistry in acyclic systems. In the reaction shown below, the internal sulfoxide captures the bromonium ion and then undergoes inversion at sulfur in the hydrolytic step.

Ref. 42

A procedure that is useful for the preparation of both bromohydrins and iodohydrins involves in situ generation of the hypohalous acid from NaBrO_3 or NaIO_4 by reduction with bisulfite.⁴³

These reactions show the same regioselectivity and stereoselectivity as other reactions that proceed through halonium ion intermediates.

Because of its high reactivity, special precautions must be taken with reactions of fluorine and its use is somewhat specialized.⁴⁴ Nevertheless, there is some basis for comparison with the less reactive halogens. Addition of fluorine to *Z*- and *E*-1-propenylbenzene is not stereospecific, but *syn* addition is somewhat favored.⁴⁵ This result is consistent with formation of a cationic intermediate.

In methanol, the solvent incorporation product is formed, as would be expected for a cationic intermediate.

These results are consistent with the expectation that fluorine would not be an effective bridging atom.

There are other reagents, such as CF_3OF and $\text{CH}_3\text{CO}_2\text{F}$, that transfer an electrophilic fluorine to double bonds. These reactions probably involve an ion pair that collapses to an addition product.

The stability of hypofluorites is improved in derivatives having electron-withdrawing substituents, such as 2,2-dichloropropanoyl hypofluorite.⁴⁸ Various other fluorinating agents have been developed and used, including *N*-fluoropyridinium salts such as the

triflate⁴⁹ and heptafluorodiborate.⁵⁰ The reactivity of these reagents can be “tuned” by varying the pyridine ring substituents. In contrast to the hypofluorites, these reagents are storable.⁵¹ In nucleophilic solvents such as acetic acid or alcohols, the reagents give addition products, whereas in nonnucleophilic solvents, alkenes give substitution products resulting from deprotonation of a carbocation intermediate.

Addition of iodine to alkenes can be accomplished by a photochemically initiated reaction. Elimination of iodine is catalyzed by excess iodine, but the diiodo compounds can be obtained if unreacted iodine is removed.⁵²

The diiodo compounds are very sensitive to light and are seldom used in syntheses.

The elemental halogens are not the only sources of electrophilic halogen, and for some synthetic purposes other “positive halogen” compounds may be preferable as electrophiles. The utility of *N*-bromosuccinimide in formation of bromohydrins was mentioned earlier. Both *N*-chlorosuccinimide and *N*-bromosuccinimide transfer electrophilic halogen with the succinimide anion acting as the leaving group. As this anion is subsequently protonated to give the weak nucleophile succinimide, these reagents favor nucleophilic additions by solvent and cyclization reactions because there is no competition from a halide anion. Other compounds that are useful for specific purposes are indicated in Table 4.2. Pyridinium hydrotribromide (pyridinium hydrobromide perbromide), benzyltrimethyl ammonium tribromide, and dioxane-bromine are examples of complexes of bromine in which its reactivity is somewhat attenuated, resulting in increased selectivity. In 2,4,4,6-tetrabromocyclohexadienone is a very mild and selective source of electrophilic bromine; the leaving group is 2,4,6-tribromophenoxide ion.

Electrophilic iodine reagents are extensively employed in iodocyclization (see Section 4.2.1). Several salts of pyridine complexes with I^+ such as *bis*-(pyridinium)iodonium tetrafluoroborate and *bis*-(collidine)iodonium hexafluorophosphate have proven especially effective.⁵³

4.1.5. Addition of Other Electrophilic Reagents

Many other halogen-containing compounds react with alkenes to give addition products by mechanisms similar to halogenation. A complex is generated and the halogen is transferred to the alkene to generate a bridged cationic intermediate. This may be a symmetrical halonium ion or an unsymmetrically bridged species, depending on the ability of the reacting carbon atoms to accommodate positive charge. The direction of opening of the bridged intermediate is usually governed by electronic factors. That is, the addition is completed by attack of the nucleophile at the more positive carbon atom of the bridged intermediate. The regiochemistry of addition therefore follows Markovnikov's rule. The stereochemistry of addition is usually *anti*, because of the involvement of a bridged halonium intermediate.⁵⁴ Several reagents of this type are listed in Entries 1 to 6 of Scheme 4.2. The nucleophilic anions include isocyanate, azide, thiocyanate, and nitrate.

Entries 7 to 9 involve other reagents that react by similar mechanisms. In the case of thiocyanogen chloride and thiocyanogen, the formal electrophile is $[NCS]^+$. The presumed intermediate is a cyanothiairanium ion. The thiocyanate anion is an

ambident nucleophile and both carbon-sulfur and carbon-nitrogen bond formation can be observed, depending upon the reaction conditions (see Entry 7 in Scheme 4.2).

For nitrosyl chloride (Entry 8) and nitrosyl formate (Entry 9), the electrophile is the nitrosonium ion NO⁺. The initially formed nitroso compounds can dimerize or isomerize to the more stable oximes.

4.1.6. Addition Reactions with Electrophilic Sulfur and Selenium Reagents

Compounds having divalent sulfur and selenium atoms bound to more electronegative elements react with alkenes to give addition products. The mechanism is similar to that in halogenation and involves of bridged cationic intermediates.

In many synthetic applications, the sulfur or selenium substituent is subsequently removed by elimination, as is discussed in Chapter 6.

A variety of electrophilic reagents have been employed and several examples are given in Scheme 4.3. The sulfonylation reagents are listed in Section A. Both aryl and alkyl sulfonyl chlorides are reactive (Entries 1 and 2). Dimethyl(methylthio)sulfonium fluoroborate (Entry 3) uses dimethyl sulfide as a leaving group and can be utilized to effect capture of hydroxylic solvents and anionic nucleophiles, such as acetate and cyanide. Entries 4 and 5 are examples of *sulfenamides*, which normally require a Lewis acid catalyst to react with alkenes. Entry 6 represents application of the *Pummerer rearrangement* for in situ generation of a sulfonylation reagent. Sulfoxides react with acid anhydrides to generate sulfonium salts. When a *t*-alkyl group is present, fragmentation occurs and a sulfenylium ion is generated.⁵⁵ TFAA is the preferred anhydride in this application.

The selenylation reagents include the arylselenenyl chlorides and bromides (Entries 7 and 8), selenylium salts with nonnucleophilic counterions (Entry 9), and selenenyl trifluoroacetates, sulfates, and sulfonates (Entries 10 to 13). Diphenyl-diselenide reacts with several oxidation reagents to transfer electrophilic phenylselenenylium ions (Entries 14 to 16). *N*-Phenylselenenylphthalimide is a useful synthetic reagent that has the advantage of the nonnucleophilicity of the phthalimido leaving group (Entry 18). The hindered selenenyl bromide in Entry 19 is useful for selenylcyclizations (see Section 4.2.2).

Selenylation can also be done under conditions in which another nucleophilic component of the reaction captures the selenium-bridged ion. For

Ref. 57

In the absence of better nucleophiles, solvent can be captured, as in selenenylation, which occurs in acetonitrile.

Ref. 58

When reactions with phenylselenenyl chloride are carried out in aqueous acetonitrile solution, β -hydroxyselenides are formed as the result of solvolysis of the chloride.⁵⁹

Mechanistic studies have been most thorough with the sulfonyl halides.⁶⁰ The reactions show moderate sensitivity to alkene structure, with ERGs on the alkene accelerating the reaction. The addition can occur in either the Markovnikov or anti-Markovnikov sense.⁶¹ The variation in regioselectivity can be understood by focusing attention on the sulfur-bridged intermediate, which may range from being a sulfonium ion to a less electrophilic chlorosulfurane.

Compared to a bromonium ion, the C–S bonds are stronger and the TS for nucleophilic addition is reached later. This is especially true for the sulfurane structures. Steric interactions that influence access by the nucleophile are a more important factor in determining the direction of addition. For reactions involving phenylsulfonyl chloride or methylsulfonyl chloride, the intermediate is a fairly stable species and ease of approach by the nucleophile is the major factor in determining the direction of ring opening. In these cases, the product has the anti-Markovnikov orientation.⁶²

Terminal alkenes react with selenenyl halides with Markovnikov regioselectivity.⁶⁴ However, the β -selenyl halide addition products readily rearrange to the isomeric products.⁶⁵

4.2. Electrophilic Cyclization

When unsaturated reactants contain substituents that can participate as nucleophiles, electrophilic reagents frequently bring about cyclizations. Groups that can act as internal nucleophiles include carboxy and carboxylate, hydroxy, amino and amido, as well as carbonyl oxygen. There have been numerous examples of synthetic application of these electrophilic cyclizations.⁶⁶ The ring-size preference is usually $5 > 6 > 3 > 4$, but there are exceptions. Both the ring-size preference and the stereoselectivity reactions can usually be traced to structural and conformational features of the cyclization TS. Baldwin called attention to the role of stereoelectronic factors in cyclization reactions.⁶⁷ He classified cyclization reactions as *exo* and *endo* and as *tet*, *trig*, and *dig*, according to the hybridization at the cyclization center. The cyclizations are also designated by the size of the ring being formed. For any given separation ($n = 1, 2, 3$, etc.) of the electrophilic and nucleophilic centers, either an *exo* or *endo* mode of cyclization is usually preferred. The preferences for cyclization at trigonal centers are $5\text{-endo} \gg 4\text{-exo}$ for $n = 2$; $5\text{-exo} > 6\text{-endo}$ for $n = 3$; and $6\text{-exo} \gg 7\text{-endo}$ for $n = 4$. These relationships are determined by the preferred trajectory of the nucleophile to the electrophilic center. Substituents can affect the TS structure by establishing a preferred conformation and by electronic or steric effects.

⁶⁷. J. E. Baldwin, *J. Chem. Soc., Chem. Commun.*, 734, 738 (1976).

Electrophilic cyclizations are useful for closure of a variety of oxygen-, nitrogen-, and sulfur-containing rings. The product structure depends on the ring size and the *exo-endo* selectivity. The most common cases are formation of five- and six-membered rings.

4.2.1. Halocyclization

Brominating and iodinating reagents effect cyclization of alkenes that have a nucleophilic group situated to permit formation of five-, six-, and, in some cases, seven-membered rings. Hydroxy and carboxylate groups are the most common nucleophiles, but the reaction is feasible for any nucleophilic group that is compatible with the electrophilic halogen source. Amides and carbamates can react at either oxygen or nitrogen, depending on the relative proximity. Sulfonamides are also potential nitrogen nucleophiles. Carbonyl oxygens can act as nucleophiles and give stable products by α -deprotonation.

Intramolecular reactions usually dominate intermolecular addition for favorable ring sizes. Semiempirical (AM1) calculations found the intramolecular TS favorable to a comparable intermolecular reaction.⁶⁸ (See Figure 4.1) The intramolecular TS, which is nearly 4 kcal/mol more stable, is quite productlike with a C—O bond distance of 1.6 Å, and a bond order of 0.62. The bromonium ion bridging is unsymmetrical and fairly weak. The bond parameters for the intra- and intermolecular TSs are quite similar.

In general, cyclization can be expected in compounds having the potential for formation of five- or six-membered rings. In addition to the more typical bromination reagents, such as those listed in Table 4.2, the combination of trimethylsilyl bromide, a tertiary amine, and DMSO can effect bromolactonization.

The *anti* addition is a kinetically controlled process that results from irreversible back-side opening of an iodonium ion intermediate by the carboxylate nucleophile. Bartlett and co-workers showed that the more stable *trans* product was obtained under acidic conditions in which there is acid-catalyzed equilibration (thermodynamic control).⁷⁴

Ref. 75

Under kinetic conditions, iodolactonization reflects reactant conformation. Several cases illustrate how the stereoselectivity of iodolactonization can be related to reactant conformation. For example, the high stereoselectivity of **1** corresponds to proximity of the carboxylate group to one of the two double bonds in the preferred reactant conformation.⁷⁶

Similarly, with reactants **2** and **3** conformational preference dominates in the selectivity between CO_2^- and CH_2OH as the internal nucleophile. This conformational preference even extends to CO_2CH_3 , which can cyclize in preference to CH_2OH when it is in the conformationally preferred position.⁷⁷

On the other hand, when the competition is between a monosubstituted and a disubstituted double bond, the inherent reactivity difference between the two double bonds overcomes reactant conformational preferences.⁷⁸

Several other nucleophilic functional groups can be induced to participate in iodocyclization reactions. *t*-Butyl carbonate esters cyclize to diol carbonates.⁷⁹

Lithium salts of carbonate monoesters can also be cyclized.⁸⁰

Enhanced stereoselectivity has been found using IBr , which reacts at a lower temperature.⁸¹ (Compare Entries 6 and 7 in Scheme 4.4.) Other reagent systems that generate electrophilic iodine, such as $KI + KHSO_5$,⁸² can be used for iodocyclization.

Analogous cyclization reactions are induced by brominating reagents but they tend to be less selective than the iodocyclizations.⁸³ The bromonium ion intermediates are much more reactive and less selective.

The iodocyclization products have a potentially nucleophilic oxygen substituent β to the iodide, which makes them useful in stereospecific syntheses of epoxides and diols.

Ref. 48

Ref. 84

Positive halogen reagents can cyclize γ - and δ -hydroxyalkenes to tetrahydrofuran and tetrahydropyran derivatives, respectively.⁸⁵ Iodocyclization of homoallylic alcohols generates 3-iodotetrahydrofurans when conducted in anhydrous acetonitrile.⁸⁶ The reactions are stereospecific, with the *E*-alcohols generating the *trans* and the *Z*-isomer the *cis* product. These are *endo*-5 cyclizations, which are preferred to *exo*-4 reactions.

With the corresponding secondary alcohols, the preferred cyclization is via a conformation with a pseudoequatorial conformation.

Entry 2 is a 5-*exo* bromocyclization. The reaction in Entry 3 involves formation of a δ -lactone in an acyclic system. This reaction was carried out under conditions that lead to the thermodynamically favored *trans* isomer. Entry 4 shows typical iodolactonization conditions and illustrates both the *anti* stereoselectivity and preference for formation of five-membered rings. In Entry 5, a six-membered lactone is formed, again with *anti* stereospecificity. Entry 6 is a cyclization of a *t*-butyl carbonate ester. The selectivity between the two double bonds is the result of the relative proximity of the nucleophilic group. Entry 7 is a closely related reaction, but carried out at a much lower temperature by the use of IBr. The *cis:trans* ratio was improved to nearly 26:1. The ratio was also solvent dependent, with toluene being the best solvent. Entry 8 is a variation using a lithium carbonate as the nucleophile. Entries 9 and 10 involve hydroxy groups as nucleophiles. Entry 9 is a 6-*endo* iodocyclization. In Entry 10, a primary hydroxy group serves as the nucleophile. Entry 11 is another cyclization involving a hydroxy group, in this case forming a 7-oxabicyclo[2.2.1]heptane structure. Entry 12 is a rather unusual 5-*endo* cyclization.

Entry 13 shows cyclization with concomitant loss of the benzyloxycarbonyl group. The TS for this reaction is 5-*exo* with conformation determined by the pseudoequatorial position of the methyl group.

Entry 14 involves formation of a lactam by cyclization of a *bis*-trimethylsilylimidate. The stereoselectivity parallels that of iodolactonization.

Entries 15 to 18 are examples of use of iodocyclization in multistep syntheses. In Entry 15, iodolactonization was followed by elimination of HI from the bicyclic lactone. In Entry 16, a cyclic peroxide group remained unaffected by the standard iodolactonization and subsequent Bu_3SnH reductive deiodination. (See Section 5.5 for

a discussion of this reaction.) In Entry 17, the primary iodo substituent was replaced by a benzoate group. In Entry 18, the reactant was prepared with high *anti* selectivity by an auxiliary-directed aldol reaction. The acyloxazolidinone auxiliary then participated in the iodocyclization and was cleaved in the process.

The reaction in Entry 19 was effected using NBS.

4.2.2. Sulfenylcyclization and Selenenylcyclization

Reactants with internal nucleophiles are also subject to cyclization by electrophilic sulfur reagents, a reaction known as *sulfenylcyclization*.⁹² As for iodolactonization, unsaturated carboxylic acids give products that result from *anti* addition.⁹³

Similarly, alcohols undergo cyclization to ethers.

The corresponding reactions using selenium electrophiles are called Selenenylcyclization.^{94,95} Carboxylate (selenylactonization), hydroxy (selenyletherification), and nitrogen (selenylamidation) groups can all be captured in appropriate cases.

Internal nucleophilic capture of seleniranium ion is governed by general principles similar to those of other electrophilic cyclizations.⁹⁶ The stereochemistry of cyclization can usually be predicted on the basis of a cyclic TS with favored pseudoequatorial orientation of the substituents.

Although *exo* cyclization is usually preferred, there is no strong prohibition of *endo* cyclization and aryl-controlled regioselectivity can override the *exo* preference.

Ref. 97

93:7

Ref. 98

Various electrophilic selenium reagents such as those described in Scheme 4.3 can be used. *N*-Phenylselenenylphthalimide is an excellent reagent for this process and permits the formation of large ring lactones.⁹⁹ The advantage of the reagent in this particular application is the low nucleophilicity of phthalimide, which does not compete with the remote internal nucleophile. The reaction of phenylselenenyl chloride or *N*-phenylselenenylphthalimide with unsaturated alcohols leads to formation of β -phenylselenenyl ethers.

Ref. 100

Another useful reagent for selenenylcyclization is phenylselenenyl triflate. This reagent is capable of cyclizing unsaturated acids¹⁰¹ and alcohols.¹⁰² Phenylselenenyl sulfate can be prepared in situ by oxidation of diphenyl diselenide with ammonium peroxydisulfate.¹⁰³

Several examples of sulfenylcyclization are given in Section A of Scheme 4.5. Entry 1 is a 6-*exo* sulfenoetherification induced by phenylsulfonyl chloride. Entry 2

is mediated by dimethyl(methylthio)sulfonium tetrafluoroborate. Entries 3 and 4 are other examples of 5-*exo* cyclizations. Entries 5 and 6 involve use of sulfenamides as the electrophiles. Entry 7 shows the cyclization of a carbamate involving the carbonyl oxygen. Entry 8 is an 5-*endo* aminocyclization.

Part B of Scheme 4.5 gives some examples of cyclizations induced by selenium electrophiles. Entries 9 to 13 are various selenyletherifications. All exhibit *anti* stereochemistry. Entries 14 and 15 are selenyllactonizations. Entries 17 and 18 involve amido groups as the internal nucleophile. Entry 17 is an 5-*exo* cyclization in which the amido oxygen is the more reactive nucleophilic site, leading to an iminolactone. Geometric factors favor N-cyclization in the latter case.

Chiral selenenylating reagents have been developed and shown to be capable of effecting enantioselective additions and cyclizations. The reagent **4**, for example, achieves more than 90% enantioselectivity in typical reactions.¹⁰⁴

4.2.3. Cyclization by Mercuric Ion

Electrophilic attack by mercuric ion can effect cyclization by intramolecular capture of a nucleophilic functional group. A variety of oxygen and nitrogen nucleophiles can participate in cyclization reactions, and there have been numerous synthetic applications of the reaction. Mechanistic studies have been carried out on several alkenol systems. The ring-size preference for cyclization of 4-hexenol depends on the mercury reagent that is used. The more reactive mercuric salts favor 6-*endo* addition. It is proposed that reversal of formation of the kinetic *exo* product is responsible.¹⁰⁵ Equilibration to favor the thermodynamic addition products occurs using $\text{Hg}(\text{O}_3\text{SCF}_3)_2$ and $\text{Hg}(\text{NO}_3)_2$. The equilibration does not seem to be dependent on acid catalysis, since the thermodynamically favored product is also formed in the presence of the acid-scavenger TMU.

X	A	B	C
O ₂ CCH ₃	92	8	0
O ₂ CCF ₃	13	87	0
O ₃ SCF ₃	0	88	12
O ₃ SCF ₃ (TMU)	0	100	0
NO ₃	0	100	0

In 5-aryl-4-hexenols with ERG substituents, electronic factors outweigh the *exo* preference.¹⁰⁶ The ERG substituents increase the cationic character at C(5).

Cyclization of δ , ϵ -enols is controlled by a conformation-dependent strain in the *exo* TS.¹⁰⁷ The C(5)–C(6) bond is rotated to minimize A^{1,3} strain.

¹⁰⁶. Y. Senda, H. Kanto, and H. Itoh, *J. Chem. Soc., Perkin Trans. 2*, 1143 (1997).

¹⁰⁷. K. Bratt, A. Garavelas, P. Perlmutter, and G. Westman, *J. Org. Chem.*, **61**, 2109 (1996).

In the corresponding *E*-alkene, where this factor is not present, the cyclization is much less stereoselective. A stabilizing interaction between the siloxy oxygen and the Hg^{2+} center has also been suggested.¹⁰⁸

Reaction of $\text{Hg}(\text{O}_2\text{CCF}_3)_2$ or $\text{Hg}(\text{O}_3\text{SCF}_3)_2$ with a series of dibenzylcarbinols gave *exo* cyclization for formation of five-, six-, and seven-, but not eight-membered rings.¹⁰⁹

Benzyl carbamates have been used to form both five- and six-membered nitrogen-containing rings. The selectivity for N over O nucleophilicity in these cases is the result of the nitrogen being able to form a better ring size (5 or 6 versus 7 or 8) than the carbonyl oxygen.

Ref. 111

The trapping of the radical intermediate in demercuration by oxygen can be exploited as a method for introduction of a hydroxy substituent (see p. 295). The example below and Entries 3 and 4 in Scheme 4.6 illustrate this reaction.

Ref. 112

Cyclization induced by mercuric ion is often used in multistep syntheses to form five- and six-membered heterocyclic rings, as illustrated in Scheme 4.6. The reactions in Entries 1 to 3 involve acyclic reactants that cyclize to give *exo*-5 products. Entry 4 is an *exo*-6 cyclization. In Entries 1 and 2, the mercury is removed reductively, but in Entries 3 and 4 a hydroxy group is introduced in the presence of oxygen. Inclusion of triethylboron in the reduction has been found to improve yields (Entry 1).¹¹³

The reaction in Entry 5 was used in the syntheses of linetin, which is an aggregation pheromone of the ambrosia beetle. In Entry 6, a transannular 5-*exo* cyclization occurs. Entry 7 is an example of formation of a lactone by carboxylate capture. In this case, the product was isolated as the mercurochloride.

Some progress has been made toward achieving enantioselectivity in mercuration-induced cyclization. Several *bis*-oxazoline (BOX) ligands have been investigated. The

diphenyl BOX ligand, in conjunction with $\text{Hg}(\text{O}_2\text{CCF}_3)_2$, results in formation of tetrahydrofuran rings with 80% e.e. Other *bis*-oxazoline ligands derived from tartaric acid were screened and the best results were obtained with a 2-naphthyl ligand, which gave more than 90% e.e. in several cases.

Ref. 114

4.3. Electrophilic Substitution α to Carbonyl Groups

4.3.1. Halogenation α to Carbonyl Groups

Although the reaction of ketones and other carbonyl compounds with electrophiles such as bromine leads to substitution rather than addition, the mechanism of the reaction is closely related to electrophilic additions to alkenes. An enol, enolate, or enolate equivalent derived from the carbonyl compound is the nucleophile, and the electrophilic attack by the halogen is analogous to that on alkenes. The reaction is completed by restoration of the carbonyl bond, rather than by addition of a nucleophile. The acid- and base-catalyzed halogenation of ketones, which is discussed briefly in Section 6.4 of Part A, provide the most-studied examples of the reaction from a mechanistic perspective.

The reactions involving bromine or chlorine generate hydrogen halide and are autocatalytic. Reactions with *N*-bromosuccinimide or tetrabromocyclohexadienone do not form any hydrogen bromide and may therefore be preferable reagents in the case of acid-sensitive compounds. Under some conditions halogenation is faster than enolization. When this is true, the position of substitution in unsymmetrical ketones is governed by the relative rates of formation of the isomeric enols. In general, mixtures are formed with unsymmetrical ketones. The presence of a halogen substituent

¹¹⁴. S. H. Kang and M. Kim, *J. Am. Chem. Soc.*, **125**, 4684 (2003).

decreases the rate of acid-catalyzed enolization and thus retards the introduction of a second halogen at the same site, so monohalogenation can usually be carried out satisfactorily. In contrast, in basic solution halogenation tends to proceed to polyhalogenated products because the polar effect of a halogen accelerates base-catalyzed enolization. With methyl ketones, base-catalyzed reaction with iodine or bromine leads ultimately to cleavage to a carboxylic acid.¹¹⁵ These reactions proceed to the trihalomethyl ketones, which are susceptible to base-induced cleavage.

The reaction can also be effected with hypochlorite ion, and this constitutes a useful method for converting methyl ketones to carboxylic acids.

Ref. 116

The most common preparative procedures involve use of the halogen, usually bromine, in acetic acid. Other suitable halogenating agents include *N*-bromosuccinimide, tetrabromocyclohexadienone, and sulfuryl chloride.

Another preparatively useful procedure for monohalogenation of ketones involves reaction with cupric chloride or cupric bromide.¹²¹

Instead of direct halogenation of ketones, reactions with more reactive derivatives such as silyl enol ethers and enamines have advantages in certain cases.

There are also procedures in which the enolate is generated quantitatively and allowed to react with a halogenating agent. Regioselectivity can then be controlled by the direction of enolate formation. Among the sources of halogen that have been used under these conditions are bromine,¹²⁵ *N*-chlorosuccinimide,¹²⁶ trifluoromethanesulfonyl chloride,¹²⁷ and hexachloroethane.¹²⁸

α-Fluoroketones are made primarily by reactions of enol acetates or silyl enol ethers with fluorinating agents such as CF_3OF ,¹²⁹ XeF_2 ,¹³⁰ or dilute F_2 .¹³¹ Other fluorinating reagents that can be used include *N*-fluoropyridinium salts,¹³² 1-fluoro-4-hydroxy-1,4-diazabicyclo[2.2.2]octane,¹³³ and 1,4-difluoro-1,4-diazabicyclo[2.2.2]octane.¹³⁴ These reagents fluorinate readily enolizable carbonyl compounds and silyl enol ethers.

The α-halogenation of acid chlorides also has synthetic utility. The mechanism is presumed to be similar to ketone halogenation and to proceed through an enol. The reaction can be effected in thionyl chloride as solvent to give α-chloro, α-bromo, or α-iodo acyl chlorides, using, respectively, *N*-chlorosuccinimide, *N*-bromosuccinimide, or molecular iodine as the halogenating agent.¹³⁶ Since thionyl chloride rapidly converts carboxylic acids to acyl chlorides, the acid can be used as the starting material.

Direct chlorination can be carried out in the presence of ClSO_3H , which acts as a strong acid catalyst. These procedures use various compounds including 1,3-dinitrobenzene, chloranil, and TCNQ to inhibit competing radical chain halogenation.¹³⁷

4.3.2. Sulfenylation and Selenenylation α to Carbonyl Groups

The α-sulfenylation¹³⁸ and α-selenenylation¹³⁹ of carbonyl compounds are synthetically important reactions, particularly in connection with the introduction of

unsaturation. The products can subsequently be oxidized to sulfoxides and selenoxides that readily undergo elimination (see Section 6.8.3), generating the corresponding α,β -unsaturated carbonyl compound. Sulfenylations and selenenylations are usually carried out under conditions in which the enolate of the carbonyl compound is the reactive species. If a regiospecific enolate is generated by one of the methods described in Chapter 1, the position of sulfenylation or selenenylation can be controlled.¹⁴⁰ Disulfides are the most common sulfenylation reagents, whereas diselenides or selenenyl halides are used for selenenylation.

Scheme 4.7 gives some specific examples of these types of reactions. Entry 1 shows the use of sulfenylation followed by oxidation to introduce a conjugated double bond. Entries 2 and 3 are α -sulfenylations of a ketone and lactam, respectively, using dimethyl disulfide as the sulfenylating reagent. Entries 4 and 5 illustrate the use of alternative sulfenylating reagents. Entry 4 uses *N*-phenylsulfonylcaprolactam, which is commercially available. The reagent in Entry 5 is generated by reaction of diphenyldisulfide with chloramine-T. Entries 6 to 10 are examples of reactions of preformed enolates with diphenyl diselenide or phenylselenenyl chloride. As Entries 11 and 12 indicate, the selenenylation of ketones can also be effected by reactions of enol acetates or enol silyl ethers.

4.4. Additions to Allenes and Alkynes

Both allenes¹⁴¹ and alkynes¹⁴² require special consideration with regard to mechanisms of electrophilic addition. The attack by a proton on allene might conceivably lead to the allyl cation or the 2-propenyl cation.

An immediate presumption that the more stable allyl ion will be formed overlooks the stereoelectronic facets of the reaction. Protonation at the center carbon without rotation of one of the terminal methylene groups leads to a primary carbocation

¹⁴². W. Drenth, in *The Chemistry of Triple Bonded Functional Groups*, Supplement C2, Vol. 2, S. Patai, ed., John Wiley & Sons, New York, 1994, pp. 873–915.

that is not stabilized by resonance, because the adjacent π bond is orthogonal to the empty p orbital.

As a result, protonation both in solution¹⁴³ and gas phase¹⁴⁴ occurs at a terminal carbon to give the 2-propenyl cation, not the allylic cation.

The addition of HCl, HBr, and HI to allene has been studied in some detail.¹⁴⁵ In each case a 2-halopropene is formed, corresponding to protonation at a terminal carbon. The initial product can undergo a second addition, giving rise to 2,2-dihalopropanes. The regiochemistry reflects the donor effect of the halogen. Dimers are also formed, but we have not considered them.

The presence of a phenyl group results in the formation of products from protonation at the center carbon.¹⁴⁶

Two alkyl substituents, as in 1,1-dimethylallene, also lead to protonation at the center carbon.¹⁴⁷

These substituent effects are due to the stabilization of the carbocations that result from protonation at the center carbon. Even if allylic conjugation is not important, the aryl and alkyl substituents make the terminal carbocation more stable than the alternative, a secondary vinyl cation.

Acid-catalyzed additions to terminal alkynes follow the Markovnikov rule.

Ref. 148

The rate and selectivity of the reaction can be considerably enhanced by using an added quaternary bromide salt in 1:1 TFA: CH_2Cl_2 . Note that the reactions are quite

¹⁴³. P. Cramer and T. T. Tidwell, *J. Org. Chem.*, **46**, 2683 (1981).

¹⁴⁸. J. Cousseau, *Synthesis*, 805 (1980).

slow, even under these favorable conditions, but there is clean formation of the *anti* addition product.¹⁴⁹

Surface-mediated addition of HCl or HBr can be carried out in the presence of silica or alumina.¹⁵⁰ The hydrogen halides can be generated from thionyl chloride, oxalyl chloride, oxalyl bromide, phosphorus tribromide, or acetyl bromide. The kinetic products from HCl and 1-phenylpropyne result from *syn* addition, but isomerization to the more stable *Z*-isomer occurs upon continued exposure to the acidic conditions.

The initial addition products to alkynes are not always stable. Addition of acetic acid, for example, results in the formation of enol acetates, which are converted to the corresponding ketone under the reaction conditions.¹⁵¹

The most synthetically valuable method for converting alkynes to ketones is by mercuric ion-catalyzed hydration. Terminal alkynes give methyl ketones, in accordance with the Markovnikov rule. Internal alkynes give mixtures of ketones unless some structural feature promotes regioselectivity. Reactions with $\text{Hg}(\text{OAc})_2$ in other nucleophilic solvents such as acetic acid or methanol proceed to β -acetoxy- or β -methoxyalkenylmercury intermediates,¹⁵² which can be reduced or solvolyzed to ketones. The regiochemistry is indicative of a mercurinium ion intermediate that is opened by nucleophilic attack at the more positive carbon, that is, the additions follow the Markovnikov rule. Scheme 4.8 gives some examples of alkyne hydration reactions.

Addition of chlorine to 1-butyne is slow in the absence of light. When addition is initiated by light, the major product is *E*-1,2-dichlorobutene if butyne is present in large excess.¹⁵³

In acetic acid, both 1-pentyne and 1-hexyne give the *syn* addition product. With 2-butyne and 3-hexyne, the major products are β -chlorovinyl acetates of *E*-configuration.¹⁵⁴ Some of the dichloro compounds are also formed, with more of the *E*- than the *Z*-isomer being observed.

The reactions of the internal alkynes are considered to involve a cyclic halonium ion intermediate, whereas the terminal alkynes seem to react by a rapid collapse of a vinyl cation.

Alkynes react with electrophilic selenium reagents such as phenylselenenyl tosylate.¹⁵⁵ The reaction occurs with *anti* stereoselectivity. Aryl-substituted alkynes are regioselective, but alkyl-substituted alkynes are not.

Some of the most synthetically useful addition reactions of alkynes are with organometallic reagents, and these reactions, which can lead to carbon-carbon bond formation, are discussed in Chapter 8.

4.5. Addition at Double Bonds via Organoborane Intermediates

4.5.1. Hydroboration

Borane, BH_3 , having only six valence electrons on boron, is an avid electron pair acceptor. Pure borane exists as a dimer in which two hydrogens bridge the borons.

In aprotic solvents that can act as electron pair donors such as ethers, tertiary amines, and sulfides, borane forms Lewis acid-base adducts.

Borane dissolved in THF or dimethyl sulfide undergoes addition reactions rapidly with most alkenes. This reaction, which is known as *hydroboration*, has been extensively studied and a variety of useful synthetic processes have been developed, largely through the work of H. C. Brown and his associates.

Hydroboration is highly *regioselective* and *stereospecific*. The boron becomes bonded primarily to the *less-substituted* carbon atom of the alkene. A combination of steric and electronic effects works to favor this orientation. Borane is an electrophilic reagent. The reaction with substituted styrenes exhibits a weakly negative ρ value (-0.5).¹⁵⁶ Compared with bromination ($\rho^+ = -4.3$),¹⁵⁷ this is a small substituent effect, but it does favor addition of the electrophilic boron at the less-substituted end of the double bond. In contrast to the case of addition of protic acids to alkenes, it is the *boron, not the hydrogen, that is the more electrophilic atom*. This electronic effect is reinforced by steric factors. Hydroboration is usually done under conditions in which the borane eventually reacts with three alkene molecules to give a trialkylborane. The

second and third alkyl groups would increase steric repulsion if the boron were added at the internal carbon.

Table 4.3 provides some data on the regioselectivity of addition of diborane and several of its derivatives to representative alkenes. Table 4.3 includes data for some mono- and dialkylboranes that show even higher regioselectivity than diborane itself. These derivatives are widely used in synthesis and are frequently referred to by the shortened names shown with the structures.

Table 4.3. Regioselectivity of Diborane and Alkylboranes toward Some Alkenes

Hydroborating agent	Percent boron at less substituted carbon

f. Data for 2-methyl-1-pentene.

These reagents are prepared by hydroboration of the appropriate alkene, using control of stoichiometry to terminate the hydroboration at the desired degree of alkylation.

Hydroboration is a stereospecific *syn* addition that occurs through a four-center TS with simultaneous bonding to boron and hydrogen. The new C–B and C–H bonds are thus both formed from the same face of the double bond. In molecular orbital terms, the addition is viewed as taking place by interaction of the filled alkene π orbital with the empty p orbital on boron, accompanied by concerted C–H bond formation.¹⁵⁸

As is true for most reagents, there is a preference for approach of the borane from the less hindered face of the alkene. Because diborane itself is a relatively small molecule, the stereoselectivity is not high for unhindered alkenes. Table 4.4 gives some data comparing the direction of approach for three cyclic alkenes. The products in all cases result from *syn* addition, but the mixtures result from both the low regioselectivity and from addition to both faces of the double bond. Even 7,7-dimethylnorbornene shows only modest preference for *endo* addition with diborane. The selectivity is enhanced with the bulkier reagent 9-BBN.

Table 4.4. Stereoselectivity of Hydroboration of Cyclic Alkenes^a

	Product composition ^b

The haloboranes BH_2Cl , BH_2Br , BHCl_2 , and BHBBr_2 are also useful hydroborating reagents.¹⁵⁹ These compounds are somewhat more regioselective than borane itself, but otherwise show similar reactivity. A useful aspect of the chemistry of the haloboranes is the potential for sequential introduction of substituents at boron. The halogens can be replaced by alkoxide or by hydride. When halogen is replaced by hydride, a second hydroboration step can be carried out.

Examples of these transformations are discussed in Chapter 9, where carbon-carbon bond-forming reactions of organoboranes are covered.

Amine-borane complexes are not very reactive toward hydroboration, but the pyridine complex of borane can be activated by reaction with iodine.¹⁶⁰ The active reagent is thought to be the pyridine complex of iodoborane.

The resulting boranes can be subjected to oxidation or isolated as potassium trifluoroborates.

Catecholborane and pinacolborane, in which the boron has two oxygen substituents, are much less reactive hydroborating reagents than alkyl or haloboranes because the boron electron deficiency is attenuated by the oxygen atoms. Nevertheless, they are useful reagents for certain applications.¹⁶¹ The reactivity of catecholborane has been found to be substantially enhanced by addition of 10–20% of *N,N*-dimethylacetamide to CH_2Cl_2 .¹⁶²

Catecholborane and pinacolborane are especially useful in hydroborations catalyzed by transition metals.¹⁶³ Wilkinson's catalyst $\text{Rh}(\text{PPh}_3)_3\text{Cl}$ is among those used frequently.¹⁶⁴ The general mechanism for catalysis is believed to be similar to that for homogeneous hydrogenation and involves oxidative addition of the borane to the metal, generating a metal hydride.¹⁶⁵

Variation in catalyst and ligand can lead to changes in both regio- and enantioselectivity. For example, the hydroboration of vinyl arenes such as styrene and 6-methoxy-2-vinylnaphthalene can be directed to the internal secondary borane by use of $\text{Rh}(\text{COD})_2\text{BF}_4$ as a catalyst.¹⁶⁶ These reactions are enantioselective in the presence of a chiral phosphorus ligand.

On the other hand, iridium catalysts give very high selectivity for formation of the primary borane.¹⁶⁷ Several other catalysts have been described, including, for example, dimethyltitanocene.¹⁶⁸

Catalyzed hydroboration has proven to be valuable in controlling the stereoselectivity of hydroboration of functionalized alkenes.¹⁶⁹ For example, allylic alcohols

and ethers give mainly *syn* product when catalyzed by $\text{Rh}(\text{PPh}_3)_3\text{Cl}$, whereas direct hydroboration with 9-BBN gives mainly *anti* product.

	9-BBN		catecholborane 3 mol % $\text{Rh}(\text{PPh}_3)_3\text{Cl}$	
R	yield	<i>syn:anti</i>	yield	<i>syn:anti</i>
H	91	17:83	79	81:19
PhCH_2	82	25:75	63	80:20
TBDMS	85	13:87	79	93:7

The stereoselectivity of the catalyzed reaction appears to be associated with the complexation step, which is product determining. The preferred orientation of approach of the complex is *anti* to the oxygen substituent, which acts as an electron acceptor and more electronegative groups enhance reactivity. The preferred conformation of the alkene has the hydrogen oriented toward the double bond and this leads to a *syn* relationship between the alkyl and oxygen substituents.¹⁷⁰

The use of chiral ligands in catalysts can lead to enantioselective hydroboration. Rh-BINAP^{171} **C** and the related structure **D**¹⁷² have shown good stereoselectivity in the hydroboration of styrene and related compounds (see also Section 4.5.3).

Hydroboration is thermally reversible. B–H moieties are eliminated from alkylboranes at 160° C and above, but the equilibrium still favors of the addition products.

¹⁷². J. M. Valk, G. A. Whitlock, T. P. Layzell, and J. M. Brown, *Tetrahedron: Asymmetry*, **6**, 2593 (1995).

This provides a mechanism for migration of the boron group along the carbon chain by a series of eliminations and additions.

Migration cannot occur past a quaternary carbon, however, since the required elimination is blocked. At equilibrium the major trialkyl borane is the least-substituted terminal isomer that is accessible, since this isomer minimizes unfavorable steric interactions.

Migrations are more facile for *tetra*-substituted alkenes and occur at 50°–60° C.¹⁷⁵ Bulky substituents on boron facilitate the migration. *bis*-Bicyclo[2.2.2]octanylboranes, in which there are no complications from migrations in the bicyclic substituent, were found to be particularly useful.

Ref. 176

There is evidence that boron migration occurs intramolecularly.¹⁷⁷ A TS involving an electron-deficient π complex about 20–25 kcal above the trialkylborane that describes the migration has been located computationally.¹⁷⁸

Migration of boron to terminal positions is observed under much milder conditions in the presence of transition metal catalysts. For example, hydroboration of 2-methyl-3-hexene by pinacolborane in the presence of $\text{Rh}(\text{PPh}_3)_3\text{Cl}$ leads to the terminal boronate ester.

Ref. 179

4.5.2. Reactions of Organoboranes

The organoboranes have proven to be very useful intermediates in organic synthesis. In this section we discuss methods by which the boron atom can be replaced by hydroxy, carbonyl, amino, or halogen groups. There are also important processes that use alkylboranes in the formation of new carbon-carbon bonds. These reactions are discussed in Section 9.1.

The most widely used reaction of organoboranes is the oxidation to alcohols, and alkaline hydrogen peroxide is the reagent usually employed to effect the oxidation. The mechanism, which is outlined below, involves a series of B to O migrations of the alkyl groups. The $\text{R}-\text{O}-\text{B}$ bonds are hydrolyzed in the alkaline aqueous solution, generating the alcohol.

The stereochemical outcome is replacement of the $\text{C}-\text{B}$ bond by a $\text{C}-\text{O}$ bond with *retention of configuration*. In combination with stereospecific *syn* hydroboration, this allows the structure and stereochemistry of the alcohols to be predicted with confidence. The preference for hydroboration at the least-substituted carbon of a double bond results in the alcohol being formed with regiochemistry that is complementary to that observed by direct hydration or oxymercuration, that is, anti-Markovnikov.

Several other oxidants can be used to effect the borane to alcohol conversion. Oxone[®] ($2\text{K}_2\text{SO}_5 \cdot \text{KHSO}_4 \cdot \text{K}_2\text{SO}_4$) has been recommended for oxidations done on a

¹⁷⁹. S. Pereira and M. Srebnik, *J. Am. Chem. Soc.*, **118**, 909 (1996); S. Pereira and M. Srebnik, *Tetrahedron Lett.*, **37**, 3283 (1996).

large scale.¹⁸⁰ Conditions that permit oxidation of organoboranes to alcohols using molecular oxygen,¹⁸¹ sodium peroxycarbonate¹⁸² or amine oxides¹⁸³ as oxidants have also been developed. The reaction with molecular oxygen is particularly effective in perfluoroalkane solvents.¹⁸⁴

More vigorous oxidants such as Cr(VI) reagents effect replacement of boron and oxidation to the carbonyl level.¹⁸⁵

An alternative procedure for oxidation to ketones involves treatment of the alkylborane with a quaternary ammonium perruthenate salt and an amine oxide¹⁸⁶ (see Entry 6 in Scheme 4.9). Use of dibromoborane-dimethyl sulfide for hydroboration of terminal alkenes, followed by hydrolysis and Cr(VI) oxidation gives carboxylic acids.¹⁸⁷

The boron atom can also be replaced by an amino group.¹⁸⁸ The reagents that effect this conversion are chloramine or hydroxylamine-*O*-sulfonic acid, and the mechanism of these reactions is very similar to that of the hydrogen peroxide oxidation of organoboranes. The nitrogen-containing reagent initially reacts as a nucleophile by adding at boron and a B to N rearrangement with expulsion of chloride or sulfate ion follows. Usually only two of the three alkyl groups migrate. As in the oxidation, the migration step occurs with retention of configuration. The amine is freed by hydrolysis.

The alkene can be used more efficiently if the hydroboration is done with dimethylborane.¹⁸⁹

Secondary amines are formed by reaction of trisubstituted boranes with alkyl or aryl azides. The most efficient borane intermediates are monoalkyldichloroboranes, which are generated by reaction of an alkene with $\text{BHCl}_2 \cdot \text{Et}_2\text{O}$.¹⁹⁰ The entire sequence of steps and the mechanism of the final stages are summarized by the equation below.

This reaction has been used to prepare α -*N*-methylamino acids using $(\text{CH}_3)_2\text{BBr}$.¹⁹¹

Secondary amines can also be made using the *N*-chloro derivatives of primary amines.¹⁹²

Organoborane intermediates can also be used to synthesize alkyl halides. Replacement of boron by iodine is rapid in the presence of base.¹⁹³ The best yields are obtained using sodium methoxide in methanol.¹⁹⁴ If less basic conditions are desirable, the use of iodine monochloride and sodium acetate gives good yields.¹⁹⁵ As is the case in hydroboration-oxidation, the regioselectivity of hydroboration-halogenation is opposite to that observed by direct ionic addition of hydrogen halides to alkenes. Terminal alkenes give primary halides.

Scheme 4.9 gives some examples of the use of boranes in syntheses of alcohols, aldehydes, ketones, amines, and halides. Entry 1 demonstrates both the regioselectivity and stereospecificity of hydroboration, resulting in the formation of *trans*-2-methylcyclohexanol. Entry 2 illustrates the facial selectivity, with the borane adding *anti* to the *endo* methyl group.

Entry 3 illustrates all aspects of the regio- and stereoselectivity, with *syn* addition occurring *anti* to the dimethyl bridge in the pinene structure. The stereoselectivity in Entry 4 is the result of the preferred conformation of the alkene and approach *syn* to the smaller methyl group, rather than the 2-furyl group.

Entries 5 to 7 are examples of oxidation of boranes to the carbonyl level. In Entry 5, chromic acid was used to obtain a ketone. Entry 6 shows 5 mol % tetrapropylammonium perruthenate with *N*-methylmorpholine-*N*-oxide as the stoichiometric oxidant converting the borane directly to a ketone. Aldehydes were obtained from terminal alkenes using this reagent combination. Pyridinium chlorochromate (Entry 7) can also be used to obtain aldehydes. Entries 8 and 9 illustrate methods for amination of alkenes via boranes. Entries 10 and 11 illustrate the preparation of halides.

4.5.3. Enantioselective Hydroboration

Several alkylboranes are available in enantiomerically enriched or pure form and can be used to prepare enantiomerically enriched alcohols and other compounds available via organoborane intermediates.¹⁹⁶ One route to enantiopure boranes is by hydroboration of readily available terpenes that occur naturally in enantiomerically enriched or pure form. The most thoroughly investigated of these is *bis*-(isopinocampheyl)borane; (Ipc)₂BH, which can be prepared in 100% enantiomeric purity from the readily available terpene α -pinene.¹⁹⁷ Both enantiomers are available.

Other examples of chiral organoboranes derived from terpenes are **E**, **F**, and **G**, which are derived from longifolene,¹⁹⁸ 2-carene,¹⁹⁹ and limonene,²⁰⁰ respectively.

(Ipc)₂BH adopts a conformation that minimizes steric interactions. This conformation can be represented schematically as in **H** and **I**, where the S, M, and L substituents are, respectively, the 3-H, 4-CH₂, and 2-CHCH₃ groups of the carbocyclic structure. The steric environment at boron in this conformation is such that *Z*-alkenes encounter less steric encumbrance in TS **I** than in **H**.

The degree of enantioselectivity of (Ipc)₂BH is not high for all simple alkenes. *Z*-Disubstituted alkenes give good enantioselectivity (75–90%) but *E*-alkenes and

simple cycloalkenes give low enantioselectivity (5–30%). Interestingly, vinyl ethers exhibit good enantioselectivity for both the *E*- and *Z*-isomers.²⁰¹

Monoisocampheylborane (IpcBH_2) can be prepared in enantiomerically pure form by purification of a TMEDA adduct.²⁰² When this monoalkylborane reacts with a prochiral alkene, one of the diastereomeric products is normally formed in excess and can be obtained in high enantiomeric purity by an appropriate separation.²⁰³ Oxidation of the borane then provides the corresponding alcohol having the enantiomeric purity achieved for the borane.

As oxidation also converts the original chiral terpene-derived group to an alcohol, it is not directly reusable as a chiral auxiliary. Although this is not a problem with inexpensive materials, the overall efficiency of generation of enantiomerically pure product is improved by procedures that can regenerate the original terpene. This can be done by heating the dialkylborane intermediate with acetaldehyde. The α -pinene is released and a diethoxyborane is produced.²⁰⁴

The usual oxidation conditions then convert this boronate ester to an alcohol.²⁰⁵

The corresponding haloboranes are also useful for enantioselective hydroboration. Isopinocampheylchloroborane can achieve 45–80% e.e. with representative alkenes.²⁰⁶ The corresponding bromoborane achieves 65–85% enantioselectivity with simple alkenes when used at -78°C .²⁰⁷

Procedures for synthesis of chiral amines²⁰⁸ and halides²⁰⁹ based on chiral alkylboranes involve applying the methods discussed earlier to the enantiomerically enriched organoborane intermediates. For example, enantiomerically pure terpenes can be converted to trialkylboranes and then aminated with hydroxylaminesulfonic acid.

Ref. 210

Combining catalytic enantioselective hydroboration (see p. 342) with amination has provided certain amines with good enantioselectivity. In this procedure the catechol group is replaced by methyl prior to the amination step.

Alkynes are reactive toward hydroboration reagents. The most useful procedures involve addition of a disubstituted borane to the alkyne, which avoids complications that occur with borane and lead to polymeric structures. Catechol borane is a particularly useful reagent for hydroboration of alkynes.²¹² Protonolysis of the adduct with acetic acid results in reduction of the alkyne to the corresponding *cis*-alkene. Oxidative workup with hydrogen peroxide gives ketones via enol intermediates.

Treatment of the vinylborane with bromine and base leads to vinyl bromides. The reaction occurs with net *anti* addition, and the stereoselectivity is explained on the basis of *anti* addition of bromine followed by a second *anti* elimination of bromide and boron.

Exceptions to this stereoselectivity have been noted.²¹³

The adducts derived from catechol borane are hydrolyzed by water to vinylboronic acids. These materials are useful intermediates for the preparation of terminal vinyl iodides. Since the hydroboration is a *syn* addition and the iodinolysis occurs with retention of the alkene geometry, the iodides have the *E*-configuration.²¹⁴

The dimethyl sulfide complex of dibromoborane²¹⁵ and pinacolborane²¹⁶ are also useful for synthesis of *E*-vinyl iodides from terminal alkynes.

Other disubstituted boranes have also been used for selective hydroboration of alkynes. 9-BBN can be used to hydroborate internal alkynes. Protonolysis can be carried out with methanol and this provides a convenient method for formation of a disubstituted Z-alkene.²¹⁷

A large number of procedures that involve carbon-carbon bond formation have been developed based on organoboranes. These reactions are considered in Chapter 9.

4.6. Hydroalumination, Carboalumination, Hydrozirconation, and Related Reactions

Aluminum is the immediate congener of boron, and dialkyl and trialkyl aluminum compounds, which are commercially available, have important industrial applications. They also have some similarities with organoboranes that can be exploited for synthetic purposes. Aluminum is considerably less electronegative than boron and as a result the reagents also share characteristics with the common organometallic reagents such as organomagnesium and organolithium compounds. The addition reactions of alkenes and dialkylaluminum reagents occur much less easily than hydroboration. Only terminal or strained alkenes react readily at room temperature.²¹⁸ With internal and branched alkenes, the addition does not go to completion. Addition of dialkylalanes to alkynes occurs more readily, and the regiochemistry and stereochemistry are analogous to hydroboration. The resulting vinylalanes react with halogens with *retention of configuration* at the double bond.²¹⁹

With trialkylaluminum compounds, the addition reaction is called *carboalumination*. As discussed below, this reaction requires a catalyst to proceed.

Computational studies of both hydroalumination and carboalumination have indicated a four-center TS for the addition.²²⁰ The aluminum reagents, however, have more nucleophilic character than do boranes. Whereas the TS for hydroboration is primarily electrophilic and resembles that for attack of CH_3^+ on a double bond, the

reaction with CH_3AlH_2 has a closer resemblance to reaction of CH_3^- with ethene and the strongest interaction is with the ethene LUMO. This interpretation is consistent with relative reactivity trends in which the reactivity of alkenes decreases with increasing alkyl substitution and alkynes are more reactive than alkenes.

Effective catalysts have recently been developed for the addition of trialkyl-aluminum reagents to alkenes (carboalumination). *bis*-(Pentamethylcyclopentadienyl) zirconium dimethylide activated by *tris*-(pentafluorophenyl)boron promotes the addition of trimethylaluminum to terminal alkenes.²²¹

A chiral indene derivative, structure **K**, has been most commonly used.²²² The catalyst interacts with the trialkylaluminum to generate a bimetallic species that is the active catalyst.

The detailed mechanism of the catalysis is not known, but it is believed that the Lewis acid character of the zirconium is critical.²²³ The reaction is further accelerated by inclusion of partially hydrolyzed trialkylaluminum reagents known as alumoxanes.²²⁴

The adducts can be protonolyzed or converted to halides or alcohols.

This methodology has been used to create chiral centers in saturated hydrocarbon chains such as those found in vitamin E, vitamin K, and phytol.²²⁵

By converting the primary alcohol group to an alkene by oxidation and a Wittig reaction, the reaction can be carried out in iterative fashion to introduce several methyl groups.²²⁶

At this point in time carboalumination of alkynes has been more widely applied in synthesis. The most frequently used catalyst is $(\text{Cp})_2\text{ZrCl}_2$. It is believed that a bimetallic species is formed.²²⁷

Small amounts of water accelerate carboalumination of alkynes.²²⁸ This acceleration may be the result of formation of aluminoxanes.

As indicated by the mechanism, carboalumination is a *syn* addition. The resulting vinylalanes react with electrophiles with net retention of configuration. The electrophiles that have been used successfully include iodine, epoxides, formaldehyde, and ethyl chloroformate.²²⁹ We will also see in Chapter 8 that the vinylalanes can undergo exchange reactions with transition metals, opening routes for formation of carbon-carbon bonds.

Scheme 4.10 gives some examples of application of alkyne carboalumination in synthesis. The reaction in Entry 1 was carried out as part of a synthesis of the immunosuppressant drug FK-506. The vinyl alane was subsequently transmetalated to a cuprate reagent (see Chapter 8). In Entry 2, the vinyl alane was used as a nucleophile for opening an epoxide ring and extending the carbon chain by two atoms. In Entries 3 to 5, the vinyl alane adducts were converted to vinyl iodides. In Entry 6, the vinyl alane was converted to an “ate” reagent prior to reaction with formaldehyde.

Derivatives of zirconium with a Zr–H bond also can add to alkenes and alkynes. This reaction is known as *hydrozirconation*.²³⁰ The reagent that is used most frequently

in synthesis is *bis*-(cyclopentadienido)hydrido­zirconium(IV) chloride. Reduction of $(\text{Cp})_2\text{ZrCl}_2$ generates a reactive species that can add to alkenes and alkynes.²³¹ Various reductants such as LiAlH_4 ²³² and LiEt_3BH ²³³ can be used. Alkynes readily undergo hydrosilylation. With internal alkynes, this reagent initially gives a regioisomeric mixture but isomerization occurs to give the less sterically hindered isomer.

The adducts react with electrophiles such as NCS, NBS, and I_2 to give vinyl halides.

Ref. 234

Ref. 235

Alkenes are less reactive and reactivity decreases with increasing substitution. The adducts from internal alkenes undergo isomerization to terminal derivatives.²³⁶

Carbon-carbon bond formation from alkyl and alkenyl zirconium reagents usually involves transmetalation reactions and are discussed in Chapter 8.

Problems

(References for these problems will be found on page 1277.)

- 4.1. Predict the products, including regio- and stereochemistry, for the following reactions:

- 4.2. Bromination of 4-*t*-butylcyclohexene in methanol gives a 45:55 mixture of two compounds, each of composition $\text{C}_{11}\text{H}_{21}\text{BrO}$. Predict the structure and stereochemistry of these two products. How would you confirm your prediction?

- 4.3. Oxymercuration of 4-*t*-butylcyclohexene, followed by NaBH_4 reduction, gives *cis*-4-*t*-butylcyclohexanol and *trans*-3-*t*-butylcyclohexanol in approximately equal amounts. 1-Methyl-4-*t*-butylcyclohexanol under similar conditions gives only *cis*-4-*t*-butyl-1-methylcyclohexanol. Formulate an explanation for these observations.
- 4.4. Treatment of compound **C** with *N*-bromosuccinimide in acetic acid containing sodium acetate gives a product $\text{C}_{13}\text{H}_{19}\text{BrO}_3$. Propose a structure, including stereochemistry, and explain the basis for your proposal.

- 4.5. The hydration of 5-undecyn-2-one with HgSO_4 and H_2SO_4 in methanol is regio-selective, giving 2,5-undecadione in 85% yield. Suggest an explanation for the high regioselectivity of this internal alkyne.
- 4.6. A procedure for the preparation of allylic alcohols uses the equivalent of phenylselenenic acid and an alkene. The reaction product is then treated with *t*-butylhydroperoxide. Suggest a mechanistic rationale for this process.

- 4.7. Suggest reaction conditions or short synthetic sequences that could provide the desired compound from the suggested starting material.

4.8. Three methods for the preparation of nitroalkenes are outlined below. Describe the mechanism by which each of these transformations occurs.

4.9. Hydroboration-oxidation of 1,4-di-*t*-butylcyclohexene gave three alcohols: **9-A** (77%), **9-B** (20%), and **9-C** (3%). Oxidation of **9-A** gave a ketone **9-D** that was readily converted by either acid or base to an isomeric ketone **9-E**. Ketone **9-E** was the only oxidation product of alcohols **9-B** and **9-C**. What are the structures of compounds **9A–9E**?

4.10. Show how by using regioselective enolate chemistry and organoselenium reagents, you could convert 2-phenylcyclohexanone to either 2-phenyl-2-cyclohexen-1-one or 6-phenyl-2-cyclohexen-1-one.

4.11. On the basis of the mechanistic pattern for oxymercuration-demercuration, predict the structure and stereochemistry of the alcohol(s) to be expected by application of the reaction to each of the following substituted cyclohexenes.

4.12. Give the structure, including stereochemistry, of the expected products of the following reactions. Identify the critical factors that determine the regio- and stereochemistry of the reaction.

4.13. Some synthetic transformations are shown in the retrosynthetic format. Propose a short series of reactions (no more than three steps should be necessary) that could effect each conversion.

4.14. Write mechanisms for the following reactions:

4.15. 4-Pentenyl amides such as **15A** cyclize to lactams **15B** on reaction with phenyl selenenyl bromide. The 3-butenyl compound **15C**, on the other hand, cyclizes to an imino ether **15D**. What is the basis for the differing reactions?

4.16. Procedures for enantioselective preparation of α -bromo acids based on reaction of NBS with enol derivatives **16A** and **16B** have been developed. Predict the absolute configuration of the halogenated compounds produced from both **16A** and **16B**. Explain the basis of your prediction.

4.17. The stereochemical outcome of the hydroboration-oxidation of 1,1'-bicyclohexenyl depends on the amount of diborane used. When 1.1 equivalent

is used, the product is a 3:1 mixture of **17A** and **17B**. When 2.1 equivalent is used, **17A** is formed nearly exclusively. Offer an explanation of these results.

4.18. Predict the absolute configuration of the products obtained from the following enantioselective hydroborations.

4.19. The regioselectivity and stereoselectivity of electrophilic additions to 2-benzyl-3-azabicyclo[2.2.1]hept-5-en-3-one are quite dependent on the specific electrophile. Discuss the factors that could influence the differing selectivity patterns that are observed.

4.20. Offer mechanistic explanations of the following observations:

- a. In the cyclization reactions shown below, **20A** is the preferred product for R = H, but **20B** is the preferred product for R = methyl or phenyl.

- b. The pent-4-enoyl group has been developed as a protecting group for primary and secondary amines. The conditions for cleavage involve treatment with iodine and an aqueous solution with either THF or acetonitrile as the cosolvent. Account for the mild deprotection under these conditions.

- 4.21. Analyze the data below concerning the effect of allylic and homoallylic benzyloxy substituents on the regio- and stereoselectivity of hydroboration-oxidation. Propose a TS that is consistent with the results.

- 4.22. Propose an enantioselective synthesis of (+) methyl nonactate from the aldehyde shown.

- 4.23. On page 313, the effect of methyl substitution on the stereoselectivity of α,α -diallylcarboxylic acids under iodolactonization conditions was discussed. Consider the two compounds shown and construct a reaction energy profile for

each compound that illustrates the role of conformational equilibrium, facial selectivity, and substituent effects on ΔG^\ddagger on the stereochemical outcome.

- 4.24. It has been found that when δ,ϵ -enolates bearing β -siloxy substituents are subject to iodolactonization, the substituent directs the stereochemistry of cyclization in a manner opposite to an alkyl substituent. Suggest a TS structure that would account for this difference.

Reduction of Carbon-Carbon Multiple Bonds, Carbonyl Groups, and Other Functional Groups

Introduction

The subject of this chapter is reduction reactions that are especially important in synthesis. Reduction can be accomplished by several broad methods including addition of hydrogen and/or electrons to a molecule or by removal of oxygen or other electronegative substituents. The most widely used reducing agents from a synthetic point of view are molecular hydrogen and hydride derivatives of boron and aluminum, and these reactions are discussed in Sections 5.1 through 5.3. A smaller group of reactions transfers hydride from silicon or carbon, and these are the topic of Section 5.4. Certain reductions involving a free radical mechanism use silanes or stannanes as hydrogen atom donors, and these reactions are considered in Section 5.5. Other important procedures use metals such as lithium, sodium, or zinc as electron donors. Reduction by metals can be applied to carbonyl compounds and aromatic rings and can also remove certain functional groups.

Bonds, Carbonyl
Groups, and Other
Functional Groups

dissolving metals

Y = halogen, oxygen substituents,
α-to carbonyl groups

hydrogen atom donors

Y = halogen, thio ester
Z = Sn, Si

There are also procedures that form carbon-carbon bonds. Most of these reactions begin with an electron transfer that generates a radical intermediate, which then undergoes a coupling or addition reaction. These reactions are discussed in Section 5.6.

Reductive removal of oxygen from functional groups such as ketones and aldehydes, alcohols, α-oxy ketones, and diols are also important in synthesis. These reactions, which provide important methods for interconversion of functional groups, are considered in Section 5.7

5.1. Addition of Hydrogen at Carbon-Carbon Multiple Bonds

The most widely used method for adding the elements of hydrogen to carbon-carbon double bonds is catalytic hydrogenation. Except for very sterically hindered alkenes, this reaction usually proceeds rapidly and cleanly. The most common catalysts are various forms of transition metals, particularly platinum, palladium, rhodium, ruthenium, and nickel. Both the metals as finely dispersed solids or adsorbed on inert supports such as carbon or alumina (*heterogeneous catalysts*) and certain soluble complexes of these metals (*homogeneous catalysts*) exhibit catalytic activity. Depending upon conditions and catalyst, other functional groups are also subject to reduction under these conditions.

5.1.1. Hydrogenation Using Heterogeneous Catalysts

The mechanistic description of catalytic hydrogenation of alkene is somewhat imprecise, partly because the reactive sites on the metal surface are not as well

described as small-molecule reagents in solution. As understanding of the chemistry of soluble hydrogenation catalysts developed, it became possible to extrapolate the mechanistic concepts to heterogeneous catalysts. It is known that hydrogen is adsorbed onto the metal surface, forming metal hydrogen bonds similar to those in transition metal hydrides. Alkenes are also adsorbed on the catalyst surface and at least three types of intermediates have been implicated in hydrogenation. The initially formed intermediate is pictured as attached at both carbon atoms of the double bond by π -type bonding, as shown in **A**. The bonding involves an interaction between the alkene π and π^* orbitals with corresponding acceptor and donor orbitals of the metal. A hydride can be added to the adsorbed group, leading to **B**, which involves a σ -type carbon-metal bond. This species can react with another hydrogen to give the alkane, which is desorbed from the surface. A third intermediate species, shown as **C**, accounts for double-bond isomerization and the exchange of hydrogen that sometimes accompanies hydrogenation. This intermediate is equivalent to an allyl group bound to the metal surface by π bonds. It can be formed from adsorbed alkene by abstraction of an allylic hydrogen atom by the metal. The reactions of transition metals with organic compounds are discussed in Chapter 8. There are well-characterized examples of structures corresponding to each of the intermediates **A**, **B**, and **C** that are involved in hydrogenation. However, one issue that is left unresolved by this mechanism is whether there is cooperation between adjacent metal atoms, or if the reactions occur at a single metal center, which is usually the case with soluble catalysts.

Catalytic hydrogenations are usually very clean reactions with little by-product formation, unless reduction of other groups is competitive, but careful study reveals that sometimes double-bond migration takes place in competition with reduction. For example, hydrogenation of 1-pentene over Raney nickel is accompanied by some isomerization to both *E*- and *Z*-2-pentene.¹ The isomerized products are converted to pentane, but at a slower rate than 1-pentene. Exchange of hydrogen atoms between the reactant and adsorbed hydrogen can be detected by isotopic exchange. Allylic positions undergo such exchange particularly rapidly.² Both the isomerization and allylic hydrogen exchange can be explained by the intervention of the π -allyl intermediate **C** in the general mechanism for hydrogenation. If hydrogen is added at the alternative end of the allyl system, an isomeric alkene is formed. Hydrogen exchange occurs if a hydrogen from the metal surface, rather than the original hydrogen, is transferred prior to desorption.

In most cases, both hydrogen atoms are added to the same face of the double bond (*syn* addition). If hydrogenation occurs by addition of hydrogen in two steps, as

¹ H. C. Brown and C. A. Brown, *J. Am. Chem. Soc.*, **85**, 1005 (1963).

² G. V. Smith and J. R. Swoap, *J. Org. Chem.*, **31**, 3904 (1966).

implied by the above mechanism, the intermediate must remain bonded to the metal surface in such a way that the stereochemical relationship is maintained. Adsorption to the catalyst surface normally involves the less sterically congested side of the double bond, and as a result hydrogen is added from the less hindered face of the double bond. There are many hydrogenations in which hydrogen addition is not entirely *syn*, and independent corroboration of the stereochemistry is normally necessary.

Scheme 5.1 illustrates some hydrogenations in which the *syn* addition from the less hindered side is observed. Some exceptions are also included. Entry 1 shows the hydrogenation of an exocyclic methylene group. This reaction was studied at various H_2 pressures and over both Pt and Pd catalysts. 4-Methyl- and 4-*t*-butylmethylene cyclohexane also give mainly the *cis* product.³ These results are consistent with a favored (2.3:1) equatorial delivery of hydrogen.

The Entry 2 reactant, 1,2-dimethylcyclohexene, was also studied by several groups and a 2:1–4:1 preference for *syn* addition was noted, depending on the catalyst and conditions. In the reference cited, the catalyst was prepared by reduction of a Pt salt with $NaBH_4$. A higher ratio of the *cis* product was noted at $0^\circ C$ (5.2:1) than at $25^\circ C$ (2.5:1). In Entry 3, the 2,6-dimethylcyclohexene gives mainly *cis* product with a Pt catalyst but *trans* product dominates with a Pd catalyst. These three cases indicate that stereoselectivity for unhindered alkenes is modest and dependent on reaction conditions. Entries 4 and 5 involve more rigid and sterically demanding alkenes. In both cases, *syn* addition of hydrogen occurs from the less hindered face of the molecule. Entries 6 to 8 are cases in which hydrogen is added from the more-substituted face of the double bond. The compound in Entry 6 gives mainly *trans* product at high H_2 pressure, where the effects of alkene isomerization are minimized. This result indicates that the primary adsorption must be from the methyl-substituted face of the molecule. This may result from structural changes that occur on bonding to the catalyst surface. In the *cis* approach, the methyl substituent moves away from the cyclopentane ring as rehybridization of the double bond occurs. In the *trans* approach, the methyl group must move closer to the adjacent cyclopentane ring.

The preference for addition from the more hindered of the substituents in Entries 7 and 8 can be attributed to functional group interactions with the catalyst. Polar

groups sometimes favor *cis* addition of hydrogen, relative to the substituent. This is a very common observation for hydroxy groups, but less so for esters (*vide infra*).

The facial stereoselectivity of hydrogenation is affected by the presence of polar functional groups that can govern the mode of adsorption to the catalyst surface. For instance, there are many examples of hydrogen being introduced from the face of the molecule occupied by the hydroxy group, which indicates that the hydroxy group interacts with the catalyst surface. This behavior can be illustrated with the alcohol **1a** and the ester **1b**.⁴ Although the overall shapes of the two molecules are similar, the alcohol gives mainly the product with a *cis* ring juncture (**2a**), whereas the ester gives a product with *trans* stereochemistry (**3b**). The stereoselectivity of hydroxy-directed hydrogenation is a function of solvent and catalyst. The *cis*-directing effect is strongest in nonpolar solvents such as hexane. This is illustrated by the results from compound **4**. In ethanol, the competing interaction of the solvent molecules evidently swamps out the effect of the hydroxymethyl group.

Thompson and co-workers have explored the range of substituents that can exert directive effects using polycyclic systems. For ring system **1**, hydroxymethyl and formyl showed strong directive effects; cyano, oximino, and carboxylate were moderate; and carboxy, ester, amide, and acetyl groups were not directive (see Table 5.1).^{4,5} As with **4**, the directive effects were shown to be solvent dependent. Strong donor solvents, such as ethanol and DMF, minimized the substituent-directing effect. Similar studies were carried out with ring system **5**.⁶ The results are given in Table 5.1. It would be expected that the overall shape of the reactant molecule would influence the effectiveness of the directive effect. The trends in ring systems **1** and **5** are similar, although ring system **5** appears to be somewhat less susceptible to directive effects. These hydrogenations were carried out in hydroxylic solvents and it would be expected that the directive effects would be enhanced in less polar solvents.

SECTION 5.1

Addition of Hydrogen at
Carbon-Carbon Multiple
Bonds

The general ordering of aminomethyl > hydroxymethyl > CH=O > ester suggests that Lewis basicity is the dominant factor in the directive effect. Problem 5.2 involves considering the ordering of the various acyl substituents in more detail.

Substituted indenenes provide other examples of substituent directive effects. Over Pd-alumina, the indenols **6a-c** show both *cis* stereoselectivity and a *syn* directive effect. The directive effect is reinforced by steric effects as the alkyl group becomes larger.⁷

Several indanes (**8**) were reduced to hexahydroindanes over Rh-Al₂O₃. The stereochemistry of the ring junction is established at the stage of the reduction of the tetrasubstituted double bonds. Only the amino group shows a strong directive effect.⁸

5.1.2. Hydrogenation Using Homogeneous Catalysts

In addition to solid transition metals, numerous soluble transition metal complexes are active hydrogenation catalysts.⁹ One of the first to be used was *tris*-(triphenylphosphine)rhodium chloride, known as *Wilkinson's catalyst*.¹⁰ Hydrogenation by homogeneous catalysts is believed to take place by initial formation of a π complex. The addition of hydrogen to the metal occurs by *oxidative addition* and increases the formal oxidation state of the metal by two. This is followed by transfer of hydrogen from rhodium to carbon to form an alkylrhodium intermediate. The final step is a second migration of hydrogen to carbon, leading to elimination of the saturated product (reductive elimination) and regeneration of active catalyst.

In some cases an alternative sequence involving addition of hydrogen at rhodium prior to complexation of the alkene may operate.¹¹ The phosphine ligands serve both to provide a stable soluble complex and to adjust the reactivity at the metal center. The σ -bonded intermediates have been observed for Wilkinson's catalyst¹² and for several other related catalysts.¹³ For example, a partially hydrogenated structure has been isolated from methyl α -acetamidocinnamate.¹⁴

¹⁴ J. A. Ramsden, T. D. Claridge and J. M. Brown, *J. Chem. Soc., Chem. Commun.*, 2469 (1995).

The regioselectivity of the hydride addition step has been probed by searching for deuterium exchange into isomerized alkenes that have undergone *partial* reduction.¹⁵ The results suggest that Rh is electrophilic in the addition step and that the hydride transfer is nucleophilic.

The stereochemistry of reduction by homogeneous catalysts is often controlled by functional groups in the reactant. Delivery of hydrogen occurs *cis* to a polar functional group. This behavior has been found to be particularly characteristic of an iridium-based catalyst that contains cyclooctadiene, pyridine, and tricyclohexylphosphine as ligands, known as the *Crabtree catalyst*.¹⁶ Homogeneous iridium catalysts have been found to be influenced not only by hydroxy groups, but also by amide, ester, and ether substituents.¹⁷

The Crabtree catalyst also exhibited superior stereoselectivity in comparison with other catalysts in reduction of an exocyclic methylene group.²⁰

Presumably, the stereoselectivity in these cases is the result of coordination of iridium by the functional group. The crucial property required for a catalyst to be stereodirective is that it be able to coordinate with both the directive group and the double bond and still accommodate the metal hydride bonds necessary for hydrogenation. In the iridium catalyst illustrated above, the cyclooctadiene ligand (COD) in the catalysts is released by hydrogenation, permitting coordination of the reactant and reaction with hydrogen.

Scheme 5.2 gives some examples of hydrogenations carried out with homogeneous catalysts. Entry 1 is an addition of deuterium that demonstrates net *syn* addition with the Wilkinson catalyst. The reaction in Entry 2 proceeds with high stereoselectivity and is directed by steric approach control, rather than a substituent-directing effect. One potential advantage of homogeneous catalysts is the ability to achieve a high degree of selectivity among different functional groups. Entries 3 and 4 are examples that show selective reduction of the unconjugated double bond. Similarly in Entry 5, reduction of the double bond occurs without reduction of the nitro group, which is usually rapidly reduced by heterogeneous hydrogenation. Entries 6 and 7 are cases of substituent-directed hydrogenation using the iridium (Crabtree) catalyst. The catalyst used in Entry 8 is related to the Wilkinson catalyst, but on hydrogenation of norbornadiene (NBD) has two open coordination positions. This catalyst exhibits a strong hydroxy-directing effect. The Crabtree catalyst gave excellent results in the hydrogenation of 3-methylpentadeca-4-enone to *R*-muscone. (Entry 9) A number of heterogeneous catalysts led to 5–15% racemization (by allylic exchange).

5.1.3. Enantioselective Hydrogenation

The fundamental concepts of enantioselective hydrogenation were introduced in Section 2.5.1 of Part A, and examples of reactions of acrylic acids and the important case of α -acetamido acrylate esters were discussed. The chirality of enantioselective hydrogenation catalysts is usually derived from phosphine ligands. A number of chiral phosphines have been explored in the development of enantioselective hydrogenation catalysts,²¹ and it has been found that some of the most successful catalysts are derived from chiral 1, 1'-binaphthyldiphosphines, such as BINAP.²²

Ruthenium complexes containing this ligand are able to reduce a variety of double bonds with e.e. above 95%. In order to achieve high enantioselectivity, the reactant must show a strong preference for a specific orientation when complexed with the catalyst. This ordinarily requires the presence of a functional group that can coordinate with the metal. The ruthenium-BINAP catalyst has been used successfully with unsaturated amides,²³ allylic and homoallylic alcohols,²⁴ and unsaturated carboxylic acids.²⁵

The mechanism of such reactions using unsaturated carboxylic acids and $\text{Ru}(\text{BINAP})(\text{O}_2\text{CCH}_3)_2$ is consistent with the idea that coordination of the carboxy group establishes the geometry at the metal ion.²⁶ The configuration of the new stereocenter is then established by the hydride transfer. In this particular mechanism, the second hydrogen is introduced by protonolysis, but in other cases a second hydride transfer step occurs.

This reaction has been used in the large-scale preparation of an intermediate in the synthesis of a cholesterol acyl-transferase inhibitor.²⁷

An enantioselective hydrogenation of this type is also of interest in the production of α -tocopherol (vitamin E). Totally synthetic α -tocopherol can be made in racemic form from 2,3,5-trimethylhydroquinone and racemic isophytol. The product made in this way is a mixture of all eight possible stereoisomers.

Tocopherol can be produced as the pure $2R,4'R,8'R$ stereoisomer from natural vegetable oils. This is the most biologically active of the stereoisomers. The correct side-chain stereochemistry can be obtained using a process that involves two successive enantioselective hydrogenations.²⁸ The optimum catalyst contains a 6,6'-dimethoxybiphenyl phosphine ligand. This reaction has not yet been applied to the enantioselective synthesis of α -tocopherol because the cyclization step with the phenol is not enantiospecific.

An especially important case is the enantioselective hydrogenation of α -amidoacrylic acids, which leads to α -aminoacids.²⁹ A particularly detailed study has been carried out on the mechanism of reduction of methyl *Z*- α -acetamidocinnamate by a rhodium catalyst with a chiral diphosphine ligand DIPAMP.³⁰ It has been concluded that the reactant can bind reversibly to the catalyst to give either of two complexes. Addition of hydrogen at rhodium then leads to a reactive rhodium hydride and eventually to product. Interestingly, the addition of hydrogen occurs most rapidly in the minor isomeric complex, and the enantioselectivity is due to this kinetic preference.

A thorough computational study of this process has been carried out using B3LYP/ONIOM calculations.³¹ The rate-determining step is found to be the formation of the rhodium hydride intermediate. The barrier for this step is smaller for the minor complex than for the major one. Additional details on this study can be found at:

Visual models and additional information and exercises on Asymmetric Hydrogenation can be found in the Digital Resource available at: Springer.com/carey-sundberg.

Another mechanistic study, carried out using *S*-BINAP-ruthenium(II) diacetate catalyst, concluded that the mechanism shown in Figure 5.1 was operating.³² The rate-determining step is the hydrogenolysis of intermediate **13**, which has an E_a of about 19 kcal/mol. This step also determines the enantioselectivity and proceeds with retention of configuration. The prior steps are reversible and the relative stability of **13_R** > **13_S** determines the preference for the *S*-enantiomer. The energy relationships are summarized in Figure 5.2. The major difference between the major and minor pathways is in the precursors **12_{re}** (favored) and **12_{si}** (disfavored). There is a greater steric repulsion between the carboxylate substituent and the BINAP ligand in **12_{si}** than in **12_{re}** (Figure 5.3.).

A related study with a similar ruthenium catalyst led to the structural and NMR characterization of an intermediate that has the crucial Ru—C bond in place and also shares other features with the BINAP-ruthenium diacetate mechanism.³³ This mechanism, as summarized in Figure 5.4, shows the formation of a metal hydride prior to the complexation of the reactant. In contrast to the mechanism for acrylic acids shown on p. 378, the creation of the new stereocenter occurs at the stage of the addition of the second hydrogen.

Catalyst reactivity and enantioselectivity can be affected by substituents on ligands. In the Rh-catalyzed hydrogenation of methyl *Z*- α -acetamidocinnamate, for example, BINOL phosphites with ERGs give much higher enantioselectivity than those with EWGs. The ligand substituents modify the electron density at the metal center and change the energy balance between the competing pathways. This example demonstrates the potential for fine-tuning of the catalysts by changes that are relatively remote from the catalytic site.³⁴

Many other catalysts and ligands have been examined for the enantioselective reduction of α -acetamidoacrylates and related substrates. Phosphoramidites derived from BINOL and the cyclic amines piperidine and morpholine give excellent results.³⁵

³⁴. I. Gergely, C. Hegedus, A. Szollosy, A. Monsees, T. Riermeier, and J. Bakos, *Tetrahedron Lett.*, **44**, 9025 (2003).

These ligands also give excellent results with dimethyl itaconate and α -arylenamides.

Scheme 5.3 shows the enantioselectivity of some hydrogenations of unsaturated acids and amides. Entries 1 to 5 are examples of hydrogenations of α -acetamidoacrylate and α -acetamidocinnamate esters. The catalyst in Entries 1 and 2 uses chiraphos as the chiral phosphine ligand and norbornadiene as the removable ligand. The catalyst in Entry 3 uses DIPAMP as the chiral ligand. BINAP is the ligand in Entry 4. The ligand in Entry 5, known as EtDuPHOS, gave highly selective reduction of the α,β -double bond in the conjugated system. Entries 6 and 7 show reduction of acrylate esters having other types of substituents that give good results with the DIPAMP catalyst. Entries 8 to 10 show examples of several alkylidene succinate half-esters.

There can be significant differences in the detailed structure and mechanism of these catalysts. For example, the geometry of the phosphine ligands may affect the reactivity at the metal ion, but the basic elements of the mechanism of enantioselection are similar. The phosphine ligands establish a chiral environment and provide an appropriate balance of reactivity and stability for the metal center. The reactants bind to the metal through the double bond and at least one other functional group, and mutual interaction with the chiral environment is the basis for enantioselectivity. The new stereocenters are established under the influence of the chiral environment.

The enantioselective hydrogenation of unfunctionalized alkenes presents special challenges. Functionalized reactants such as acrylate esters can coordinate with the metal in the catalyst and this point of contact can serve to favor a specific orientation and promote enantioselectivity. Unfunctionalized alkenes do not have such coordination sites and enantioselectivity is based on steric factors. A number of iridium-based catalysts have been developed. One successful type of catalyst incorporates phosphine or phosphite groups and a chiral oxazoline ring as donors.³⁶ The catalysts also incorporate cyclooctadiene as a removable ligand. These catalysts are extremely sensitive to even weakly coordinating anions and the preferred anion for alkene hydrogenation is *tetrakis*-[(3,5-trifluoromethyl)phenyl]borate. Most of the examples to date have been with aryl-substituted double bonds.

Catalyst	Percent e.e.	
A	84	96
B	94	97

These catalysts are activated by hydrogenation of the cyclooctadiene ligand, which releases cyclooctane and opens two coordination sites at iridium. The mechanism has been probed by computational studies.⁴⁰ It is suggested that the catalytic cycle involves

⁴⁰ P. Brandt, C. Hedberg, and P. G. Andersson, *Chem. Eur. J.*, **9**, 339 (2003).

the addition of two hydrogens to the alkene-catalyst complex, followed by formation of an alkyliridium intermediate and reductive elimination.

The enantioselectivity is thought to result from both steric blocking by the *t*-butyl substituent on the oxazoline ring and an attractive van der Waals interaction of an aryl ring and the oxazoline ring, as shown in Figure 5.5.

5.1.4. Partial Reduction of Alkynes

Partial reduction of alkynes to *Z*-alkenes is an important synthetic application of selective hydrogenation catalysts. The transformation can be carried out under heterogeneous or homogeneous conditions. Among heterogeneous catalysts, the one that

Fig. 5.5. Suggested basis of enantioselectivity in hydrogenation of α -methylstilbene by a phosphinoaryl oxazoline-iridium catalyst. Reproduced from *Chem. Eur. J.*, **9**, 339 (2003), by permission of Wiley-VCH.

is most successful is *Lindlar's catalyst*, a lead-modified palladium- CaCO_3 catalyst.⁴¹ A nickel-boride catalyst prepared by reduction of nickel salts with sodium hydride is also useful.⁴² Rhodium catalysts have also been reported to show good selectivity.⁴³

5.1.5. Hydrogen Transfer from Diimide

Catalytic hydrogenation transfers the elements of molecular hydrogen through a series of complexes and intermediates. Diimide, $\text{HN}=\text{NH}$, an unstable hydrogen donor that can be generated in situ, finds specialized application in the reduction of carbon-carbon double bonds. Simple alkenes are reduced efficiently by diimide, but other easily reduced functional groups, such as nitro and cyano are unaffected. The mechanism of the reaction is pictured as a concerted transfer of hydrogen via a nonpolar cyclic TS.

In agreement with this mechanism is the fact that the stereochemistry of addition is *syn*.⁴⁴ The rate of reaction with diimide is influenced by torsional and angle strain in the alkene. More strained double bonds react at accelerated rates.⁴⁵ For example, the more strained *trans* double bond is selectively reduced in *Z,E*-1,5-cyclodecadiene.

Ref. 46

Diimide selectively reduces terminal over internal double bonds in polyunsaturated systems.⁴⁷

Reduction by diimide can be advantageous when compounds contain functional groups that would be reduced by other methods or when they are unstable to hydrogenation catalysts. There are several methods for generation of diimide and they are illustrated in Scheme 5.4. The method in Entry 1 is probably the one used most frequently in synthetic work and involves the generation and spontaneous decarboxylation of azodicarboxylic acid. Entry 2, which illustrates another convenient method, thermal decomposition of *p*-toluenesulfonylhydrazide, is interesting in that it

demonstrates that the very easily reduced disulfide bond is unaffected by diimide. Entry 3 involves generation of diimide by oxidation of hydrazine and also illustrates the selective reduction of *trans* double bonds in a medium-sized ring. Entry 4 shows that nitro groups are unaffected by diimide. Entries 5 to 7 involve sensitive molecules in which double bonds are reduced successfully. Entry 8, part of a synthesis of the kopsane group of alkaloids, successfully retains a sulfur substituent. Entry 9 illustrates a more recently developed diimide source, photolysis of 1,3,4-thiadiazolin-2,5-dione. Entry 10 is a selective reduction of a *trans* double bond in a macrocyclic lactone and was used in the synthesis of epothilone analogs.⁴⁸

5.2. Catalytic Hydrogenation of Carbonyl and Other Functional Groups

Many other functional groups are also reactive under conditions of catalytic hydrogenation. Ketones, aldehydes, and esters can all be reduced to alcohols, but in most cases these reactions are slower than alkene reductions. For most synthetic applications, the hydride transfer reagents, discussed in Section 5.3, are used for reduction of carbonyl groups. The reduction of nitro compounds to amines, usually proceeds very rapidly. Amides, imines, and also nitriles can be reduced to amines. Hydrogenation of amides requires extreme conditions and is seldom used in synthesis, but reductions of imines and nitriles are quite useful. Table 5.2 gives a summary of the approximate conditions for catalytic hydrogenation of some common functional groups.

⁴⁸. For another example, see J. D. White, R. G. Carter, and K. F. Sundermann, *J. Org. Chem.*, **64**, 684 (1999).

Table 5.2. Conditions for Catalytic Reduction of Various Functional Groups^a

Reactant	Product	Catalyst	Conditions
		Pd, Pt, Ni, Ru, Rh	Rapid at room temperature (R.T.) and 1 atm except for highly substituted or hindered cases
		Lindlar	R. T. and low pressure, quinoline or lead added to deactivate catalyst
		Rh, Pt	Moderate pressure (5–10 atm), 50–100°C
		Ni, Pd	High pressure (100–200 atm), 100–200°C
		Pt, Ru	Moderate rate at R. T. and 1–4 atm. acid-catalyzed
		Cu–Cr, Ni	High pressure, 50–100°C
		Pd	R. T., 1–4 atm. acid-catalyzed
		Pd, Ni	50–100°C, 1–4 atm
		Pd	R. T., 1 atm. quinoline or other catalyst moderator used
		Pd, Ni, Ru	Very strenuous conditions required
		Cu–Cr, Ni	200°C, high pressure
		Ni, Rh	50–100°C, usually high pressure, NH3 added to increase yield of primary amine
		Cu–Cr	Very strenuous conditions required
		Pd, Ni, Pt	R. T., 1–4 atm
		Pd, Pt	R. T., 4–100 atm
		Pd	Order of reactivity: I > Br > Cl > F, bases promote reactions for R = alkyl
		Pt, Pd	Proceeds slowly at R. T., 1–4 atm, acid-catalyzed

SECTION 5.2

Catalytic Hydrogenation of Carbonyl and Other Functional Groups

a. General References: M. Freifelder, *Catalytic Hydrogenation in Organic Synthesis: Procedures and Commentary*, John Wiley & Sons, New York, 1978; P. N. Rylander, *Hydrogenation Methods*, Academic Press, Orlando FL, 1985.

Many enantioselective catalysts have been developed for reduction of functional groups, particularly ketones. BINAP complexes of Ru(II)Cl₂ or Ru(II)Br₂ give good enantioselectivity in reduction of β-ketoesters.⁴⁹ This catalyst system has been shown to be subject to acid catalysis.⁵⁰ Thus in the presence of 0.1 mol % HCl, reduction proceeds smoothly at 40 psi of H₂ at 40° C.

⁴⁹. R. Noyori, T. Ohkuma, M. Kitamura, H. Takaya, N. Sayo, H. Kumobayashi, and S. Akutagawa, *J. Am. Chem. Soc.*, **109**, 5856 (1987).

⁵⁰. S. A. King, A. S. Thompson, A. O. King, and T. R. Verhoeven, *J. Org. Chem.*, **57**, 6689 (1992).

For reduction of monofunctional ketones, the most effective catalysts include diamine ligands. The diamine catalysts exhibit strong selectivity for carbonyl groups over carbon-carbon double and triple bonds. These catalysts have a preference for equatorial approach in the reduction of cyclohexanones and for steric approach control in the reduction of acyclic ketones.⁵¹

Related catalysts include both a chiral BINAP-type phosphine and a chiral diamine ligand. A wide range of aryl ketones gave more than 95% enantioselectivity when substituted-1,1'-binaphthyl and ethylene diamines were used.⁵²

Cyclic and α,β -unsaturated ketones also gave high e.e. but straight-chain alkyl ketones did not.

The suggested catalytic cycle for the diamine catalysts indicates that the NH group of the diamine plays a direct role in the hydride transfer through a six-membered TS.⁵³ A feature of this mechanism is the absence of direct contact between the ketone and the metal. Rather, the reaction is pictured as a nucleophilic delivery of hydride from ruthenium, concerted with a proton transfer from nitrogen.

⁵³. C. A. Sandoval, T. Ohkuma, Z. Muniz, and R. Noyori, *J. Am. Chem. Soc.*, **125**, 13490 (2003).

The catalyst used for these mechanistic studies has been characterized by X-ray crystallography, as shown in Figure 5.6. It is obtained as a hydrido ruthenium(II) species that is also coordinated by a $[BH_4]^-$ anion. The catalyst is prepared by exposing the DINAP-diamine $RuCl_2$ complex to excess $NaBH_4$.⁵⁴

Fig. 5.6. Crystal structure of *tetrakis-P,P,P',P'-(4-methylphenyl)-1,1'-binaphthyldi-phosphine-1,2-diphenyl-1,2-ethanediamine ruthenium borohydride* catalyst. Reproduced from *J. Am. Chem. Soc.*, **124**, 6508 (2002), by permission of the American Chemical Society.

⁵⁴. T. Ohkuma, M. Koizumi, K. Muniz, G. Hilt, C. Kabuto, and R. Noyori, *J. Am. Chem. Soc.*, **124**, 6508 (2002).

Several other versions of these catalysts have been developed. Arene complexes of monotosyl-1,2-diphenylethylenediamine ruthenium chloride give good results with α,β -ynones.⁵⁵ The active catalysts are generated by KOH. These catalysts also function by hydrogen transfer, with isopropanol serving as the hydrogen source. Entries 6 to 8 in Scheme 5.3 are examples.

Scheme 5.5 gives some examples of the application of these Ru(II)-diphosphine and diamine catalysts. Entries 1 and 2 are examples of the hydrogenation of β -dicarbonyl compounds with Ru(BINAP)Cl₂. Excellent enantioselectivity is observed, although elevated hydrogen pressure is required. Entry 3 proceeds in fair yield and enantioselectivity, and without reduction of the conjugated carbon-carbon double bond. Entry 4 uses the cymene complex catalyst E under hydrogen transfer conditions. Entry 5 involves tandem 1,4- and 1,2-reduction and was done under hydrogen transfer conditions, using formic acid as the hydride donor. Entries 6 to 8 show good yields and enantioselectivity for several alkynyl ketones of increasing structural complexity. In the latter two cases, only a single stereoisomer was observed.

Certain functional groups can be entirely removed and replaced by hydrogen, a reaction known as *hydrogenolysis*. For example, aromatic halogen substituents are frequently removed by hydrogenation over transition metal catalysts. Aliphatic halogens are somewhat less reactive but hydrogenolysis is promoted by base.⁵⁶ The most useful type of hydrogenolysis reaction involves removal of oxygen functional groups at benzylic and allylic positions.⁵⁷

Hydrogenolysis of halides and benzylic groups presumably involves intermediates formed by *oxidative addition* to the active metal catalyst to generate intermediates similar to those involved in hydrogenation. The hydrogenolysis is completed by reductive elimination.⁵⁸ Many other examples of this pattern of reactivity are discussed in Chapter 8.

The facile cleavage of the benzyl-oxygen bond has made the benzyl group a useful protecting group in multistep syntheses. A particularly important example is the use of the carbobenzyloxy group in peptide synthesis. The protecting group is removed by hydrogenolysis. The substituted carbamic acid generated by the hydrogenolysis decarboxylates spontaneously to provide the amine (see Section 3.5.2).

5.3. Group III Hydride-Donor Reagents

5.3.1. Comparative Reactivity of Common Hydride Donor Reagents

Most reductions of carbonyl compounds are done with reagents that transfer a hydride from boron or aluminum. The various reagents of this type that are available provide a considerable degree of chemo- and stereoselectivity. Sodium borohydride and lithium aluminum hydride are the most widely used of these reagents. Sodium borohydride is a mild reducing agent that reacts rapidly with aldehydes and ketones but only slowly with esters. It is moderately stable in hydroxylic solvents and can be used in water or alcoholic solutions. Lithium aluminum hydride is a much more powerful donor reagent, and it rapidly reduces esters, acids, nitriles, and amides, as well as aldehydes and ketones. Lithium aluminum hydride is strongly basic and reacts very rapidly (*violently*) with water or alcohols to release hydrogen. It must be used in anhydrous solvents, usually ether or tetrahydrofuran. The difference in the reactivity of these two compounds is due to properties of both the cations and the anions. Lithium is a stronger Lewis acid than sodium and AlH_4^- is a more reactive hydride donor than BH_4^- . Neither sodium borohydride nor lithium aluminum hydride reacts with isolated carbon-carbon double bonds. The reactivity of these reagents and some related reducing reagents is summarized in Table 5.3.

The mechanism by which the Group III hydrides effect reduction involves activation of the carbonyl group by coordination with a metal cation and nucleophilic transfer of hydride to the carbonyl group. Hydroxylic solvents also participate in the reaction,⁵⁹ and as reduction proceeds and hydride is transferred, the Lewis acid character of boron and aluminum becomes a factor.

As all four of the hydrides can eventually be transferred, there are actually several distinct reducing agents functioning during the course of the reaction.⁶⁰ Although this somewhat complicates interpretation of rates and stereoselectivity, it does not detract from the synthetic utility of these reagents. Reduction with NaBH₄ is usually done in aqueous or alcoholic solution and the alkoxyboranes formed as intermediates are rapidly solvolyzed.

The mechanism for reduction by LiAlH₄ is very similar. However, since LiAlH₄ reacts very rapidly with protic solvents to form molecular hydrogen, reductions with this reagent must be carried out in aprotic solvents, usually ether or tetrahydrofuran.

⁶⁰ B. Rickborn and M. T. Wuesthoff, *J. Am. Chem. Soc.*, **92**, 6894 (1970).

The products are liberated by hydrolysis of the aluminum alkoxide at the end of the reaction. Lithium aluminum hydride reduction of esters to alcohols involves an elimination step in addition to hydride transfers.

Amides are reduced to amines because the nitrogen is a poorer leaving group than oxygen at the intermediate stage of the reduction. Primary and secondary amides are rapidly deprotonated by the strongly basic LiAlH_4 , so the addition step involves the conjugate base.

Reduction of amides by LiAlH_4 is an important method for the synthesis of amines.

Ref. 61

Ref. 62

Several factors affect the reactivity of the boron and aluminum hydrides, including the metal cation present and the ligands, in addition to hydride, in the complex hydride. Some of these effects can be illustrated by considering the reactivity of ketones and aldehydes toward various hydride transfer reagents. Comparison of LiAlH_4 and NaAlH_4 has shown the former to be more reactive,⁶³ which is attributed to the greater

⁶¹. A. C. Cope and E. Ciganek, *Org. Synth.*, **IV**, 339 (1963).

⁶². R. B. Moffett, *Org. Synth.*, **IV**, 354 (1963).

Lewis acid strength and hardness of the lithium cation. Both LiBH_4 and $\text{Ca}(\text{BH}_4)_2$ are more reactive than sodium borohydride. This enhanced reactivity is due to the greater Lewis acid strength of Li^+ and Ca^{2+} , compared with Na^+ . Both of these reagents can reduce esters and lactones efficiently.

Ref. 64

Ref. 65

Zinc borohydride, which is also a useful reagent,⁶⁶ is prepared by reaction of ZnCl_2 with NaBH_4 in THF. Owing to the stronger Lewis acid character of Zn^{2+} , $\text{Zn}(\text{BH}_4)_2$ is more reactive than NaBH_4 toward esters and amides and reduces them to alcohols and amines, respectively.⁶⁷ $\text{Zn}(\text{BH}_4)_2$ reduces carboxylic acids to primary alcohols.⁶⁸ The reagent also smoothly reduces α -amino acids to β -amino alcohols.⁶⁹

Sodium borohydride is sometimes used in conjunction with CeCl_3 (*Luche's reagent*).⁷⁰ The active reductants under these conditions are thought to be alkoxyborohydrides. Sodium cyanoborohydride is a useful derivative of sodium borohydride.⁷¹ The electron-attracting cyano substituent reduces reactivity and only iminium groups are rapidly reduced by this reagent.

Alkylborohydrides are also used as reducing agents. These compounds have greater steric demands than the borohydride ion and therefore are more stereoselective in situations in which steric factors come into play.⁷² These compounds are prepared by reaction of trialkylboranes with lithium, sodium, or potassium hydride.⁷³ Several of the compounds are available commercially under the trade name Selectrides®.⁷⁴

⁷⁴ Selectride is a trade name of the Aldrich Chemical Company.

Derivatives of aluminum hydrides in which one or more of the hydrides is replaced by an alkoxide ion can be prepared by addition of the calculated amount of the appropriate alcohol.

These reagents generally show increased solubility in organic solvents, particularly at low temperatures, and are useful in certain selective reductions.⁷⁵ Lithium tri-*t*-butoxyaluminum hydride and sodium *bis*-(2-methoxyethoxy)aluminum hydride (Red-Al)⁷⁶ are examples of these types of reagents that have synthetic use. Their reactivity toward carbonyl groups is summarized in Table 5.3.

Closely related to, but distinct from, the anionic boron and aluminum hydrides are the neutral boron (borane, BH_3) and aluminum (alane, AlH_3) hydrides. These molecules also contain hydrogen that can be transferred as hydride. Borane and alane differ from the anionic hydrides in being electrophilic species by virtue of the vacant p orbital and are Lewis acids. Reduction by these molecules occurs by an intramolecular hydride transfer in a Lewis acid-base complex of the reactant and reductant.

Alkyl derivatives of boron and alane can function as reducing reagents in a similar fashion. Two reagents of this type, disiamylborane and diisobutylaluminum hydride (DiBALH) are included in Table 5.3. The latter is an especially useful reagent.

Diborane also has a useful pattern of selectivity. It reduces carboxylic acids to primary alcohols under mild conditions that leave esters unchanged.⁷⁷ Nitro and cyano groups are relatively unreactive toward diborane. The rapid reaction between carboxylic acids and diborane is the result of formation of a triacyloxyborane intermediate by protonolysis of the B—H bonds. The resulting compound is essentially a mixed anhydride of the carboxylic acid and boric acid in which the carbonyl groups have enhanced reactivity toward borane or acetoxyborane.

Diborane also reduces amides to amines (see Section 5.3.1.2).

In synthesis, the principal factors that affect the choice of a reducing agent are selectivity among functional groups (chemoselectivity) and stereoselectivity. Chemoselectivity can involve two issues. One may wish to effect a *partial reduction* of a particular functional group or it may be necessary to *reduce one group in preference to another*.⁷⁸ In the sections that follow, we consider some synthetically useful partial and selective reductions.

5.3.1.1. Partial Reduction of Carboxylic Acid Derivatives. One of the more difficult partial reductions is the conversion of a carboxylic acid derivative to an aldehyde without overreduction to the alcohol. Aldehydes are inherently more reactive than acids or esters, so the challenge is to stop the reduction at the aldehyde stage. Several approaches have been used to achieve this objective. One is to replace some of the hydrogens in the hydride with more bulky groups, thus modifying reactivity by steric factors. Lithium tri-*t*-butoxyaluminum hydride is an example of this approach.⁷⁹ Sodium tri-*t*-butoxyaluminum hydride can be used to reduce acid chlorides to aldehydes without overreduction to the alcohol.⁸⁰ The excellent solubility of sodium *bis*-(2-methoxyethoxy)aluminum hydride (Red-Al) makes it a useful reagent for selective reductions. The reagent is soluble in toluene even at -70°C , and selectivity is enhanced by the low temperature. It is possible to reduce esters to aldehydes and lactones to lactols with this reagent.

Ref. 81

Ref. 82

The most widely used reagent for partial reduction of esters and lactones at the present time is diisobutylaluminum hydride (DiBAIH).⁸³ By use of a controlled amount of the reagent at low temperature, partial reduction can be reliably achieved. The selectivity results from the relative stability of the hemiacetal intermediate that is formed. The aldehyde is not liberated until the hydrolytic workup and is therefore not

⁷⁸. For more complete discussion of functional group selectivity of hydride reducing agents, see E. R. H. Walter, *Chem. Soc. Rev.*, **5**, 23 (1976).

subject to overreduction. At higher temperatures, where the intermediate undergoes elimination, diisobutylaluminum hydride reduces esters to primary alcohols.

Ref. 84

Ref. 85

Ref. 86

Selective reduction to aldehydes can also be achieved using *N*-methoxy-*N*-methylamides.⁸⁷ LiAlH_4 and DiAlH have both been used as the hydride donor. The partial reduction is again the result of the stability of the initial reduction product. The *N*-methoxy substituent leads to a chelated structure that is stable until acid hydrolysis occurs during workup.

Another useful approach to aldehydes is by partial reduction of nitriles to imines. The reduction stops at the imine stage because of the low electrophilicity of the deprotonated imine intermediate. The imines are then hydrolyzed to the aldehyde. Diisobutylaluminum hydride seems to be the best reagent for this purpose.^{88, 89}

This method can be used in conjunction with addition of cyanide to prepare α -hydroxy aldehydes from ketones.⁹⁰

5.3.1.2. Reduction of Imines and Amides to Amines. A second type of chemoselectivity arises in the context of the need to reduce one functional group in the presence of another. If the group to be reduced is more reactive than the one to be left unchanged, it is simply a matter of choosing a reducing reagent with the appropriate level of reactivity. Sodium borohydride, for example, is very useful in this respect since it reduces ketones and aldehydes much more rapidly than esters. Sodium cyanoborohydride is used to reduce imines to amines, but this reagent is only reactive toward iminium ions. At pH 6–7, NaBH_3CN is essentially unreactive toward carbonyl groups. When an amine and ketone are mixed together, equilibrium is established with the imine. At mildly acidic pH only the protonated imine is reactive toward NaBH_3CN .⁹¹ This process is called *reductive amination*.

Reductive amination by NaBH_3CN can also be carried out in the presence of $\text{Ti}(\text{O}-i\text{-Pr})_4$. These conditions are especially useful for situations in which it is not practical to use the amine in excess (as is typically done under the acid-catalyzed conditions) or for acid-sensitive compounds. The $\text{Ti}(\text{O}-i\text{-Pr})_4$ may act as a Lewis acid in generation of a tetrahedral adduct, which then may be reduced directly or via a transient iminium intermediate.⁹²

Sodium triacetoxyborohydride is an alternative to NaBH_3CN for reductive amination. This reagent can be used with a wide variety of aldehydes or ketones with primary and secondary amines, including aniline derivatives.⁹³ This reagent has been used successfully to alkylate amino acid esters.⁹⁴

This method was used in a large-scale synthesis of 1-benzyl-3-methylamino-4-methylpiperidine.⁹⁵

Zinc borohydride has been found to effect very efficient reductive amination in the presence of silica. The amine and carbonyl compound are mixed with silica and the powder is then treated with a solution of $Zn(BH_4)_2$. Excellent yields are also obtained for unsaturated aldehydes and ketones.⁹⁶

Aromatic aldehydes can be reductively aminated with the combination $Zn(BH_4)_2$ - $ZnCl_2$,⁹⁷ and the $ZnCl_2$ assists in imine formation.

Amides are usually reduced to amines using $LiAlH_4$. Amides require vigorous reaction conditions for reduction by $LiAlH_4$, so that little selectivity can be achieved with this reagent. Diborane is also a useful reagent for reducing amides. Tertiary and secondary amides are easily reduced, but primary amides react only slowly.⁹⁸ The electrophilicity of borane is involved in the reduction of amides. The boron complexes at the carbonyl oxygen, enhancing the reactivity of the carbonyl center.

Diborane permits the selective reduction of amides in the presence of ester and nitro groups.

Alane is also a useful group for reducing amides and it, too, can be used to reduce amides to amines in the presence of ester groups.

Ref. 99

The electrophilicity of alane is the basis for its selective reaction with the amide group. Alane is also useful for reducing azetidinones to azetidines. Most nucleophilic hydride reducing agents lead to ring-opened products. DiBALiH , AlH_2Cl , and AlHCl_2 can also reduce azetidinones to azetidines.¹⁰⁰

Ref. 101

Another approach to reduction of an amide group in the presence of other groups that are more easily reduced is to convert the amide to a more reactive species. One such method is conversion of the amide to an O-alkyl derivative with a positive charge on nitrogen.¹⁰² This method has proven successful for tertiary and secondary, but not primary, amides.

Other compounds that can be readily derived from amides that are more reactive toward hydride reducing agents are α -alkylthioimmonium ions¹⁰³ and α -chloroimmonium ions.¹⁰⁴

5.3.1.3. Reduction of α,β -Unsaturated Carbonyl Compounds. An important case of chemoselectivity arises in the reduction of α,β -unsaturated carbonyl compounds. Reduction can occur at the carbonyl group, giving either a saturated ketone at the double bond or an allylic alcohol. These alternative reaction modes are called 1,2- and 1,4-reduction, respectively. If hydride is added at the carbonyl group, the allylic alcohol is usually not susceptible to further reduction. If a hydride is added at the β -position, the initial product is an enolate. In protic solvents this leads to the ketone, which can be reduced to the saturated alcohol. Both NaBH_4 and LiAlH_4 have been observed to give both types of product, although the extent of reduction to saturated alcohol is usually greater with NaBH_4 .¹⁰⁵

Several reagents have been developed that lead to exclusive 1,2- or 1,4-reduction. Use of NaBH_4 in combination with cerium chloride (*Luche reagent*) results in clean 1,2-reduction.¹⁰⁶ DiBALiH ¹⁰⁷ and the dialkylborane 9-BBN¹⁰⁸ also give exclusive carbonyl reduction. In each case the reactivity of the carbonyl group is enhanced by a Lewis acid complexation at oxygen.

Selective reduction of the carbon-carbon double bond can usually be achieved by catalytic hydrogenation. A series of reagents prepared from a hydride reducing agent and copper salts also gives primarily the saturated ketone.¹⁰⁹ Similar reagents have been shown to reduce α,β -unsaturated esters¹¹⁰ and nitriles¹¹¹ to the corresponding saturated compounds. The mechanistic details are not known with certainty, but it is likely that “copper hydrides” are the active reducing agents and that they form an organocopper intermediate by conjugate addition.

Combined use of $\text{Co}(\text{acac})_2$ and DIBALH also gives selective reduction for α,β -unsaturated ketones, esters, and amides.¹¹² Another reagent combination that selectively reduces the carbon-carbon double bond is Wilkinson's catalyst and triethylsilane. The initial product is the enol silyl ether.¹¹³

Unconjugated double bonds are unaffected by this reducing system.¹¹⁴

The enol ethers of β -dicarbonyl compounds are reduced to α,β -unsaturated ketones by LiAlH_4 , followed by hydrolysis.¹¹⁵ Reduction stops at the allylic alcohol, but subsequent acid hydrolysis of the enol ether and dehydration leads to the isolated product. This reaction is a useful method for synthesis of substituted cyclohexenones.

5.3.2. Stereoselectivity of Hydride Reduction

5.3.2.1. Cyclic Ketones. Stereoselectivity is a very important aspect of reductions by hydride transfer reagents. The stereoselectivity of the reduction of carbonyl groups is affected by the same combination of steric and stereoelectronic factors that control the addition of other nucleophiles, such as enolates and organometallic reagents to carbonyl groups. A general discussion of these factors is given in Section 2.4.1 of Part A. The stereochemistry of hydride reduction has been thoroughly studied with conformationally biased cyclohexanones. Some reagents give predominantly axial cyclohexanols, whereas others give the equatorial isomer. Axial alcohols are most likely to be formed when the reducing agent is a sterically hindered hydride donor because the equatorial direction of approach is more open and is preferred by bulky reagents. This is called *steric approach control*.¹¹⁶

With less hindered hydride donors, particularly NaBH_4 and LiAlH_4 , conformationally biased cyclohexanones give predominantly the equatorial alcohol, which is normally the more stable of the two isomers. However, hydride reductions are exothermic reactions with low activation energies. The TS should resemble starting ketone, so product stability should not control the stereoselectivity. A major factor in the preference for the equatorial isomer is the torsional strain that develops in the formation of the axial alcohol.¹¹⁷

An alternative interpretation is that the carbonyl group π -antibonding orbital, which acts as the LUMO in the reaction, has a greater density on the axial face.¹¹⁸ At the present time the importance of such orbital effects is not entirely clear. Most of the stereoselectivities that have been reported can be reconciled with torsional and steric effects being dominant.¹¹⁹

A large amount of data has been accumulated on the stereoselectivity of reduction of cyclic ketones.¹²⁰ Table 5.4 compares the stereoselectivity of reduction of several ketones by hydride donors of increasing steric bulk. The trends in the table illustrate

the increasing importance of steric approach control as both the hydride reagent and the ketone become more highly substituted. The alkyl borohydrides have especially high selectivity for the least hindered direction of approach.

When a ketone is relatively hindered, as, for example, in the bicyclo[2.2.1]heptan-2-one system, steric approach control governs stereoselectivity even for small hydride donors.

The $\text{NaBH}_4\text{-CeCl}_3$ reagent has been observed to give hydride delivery from the more hindered face of certain bicyclic ketones.¹²¹

Table 5.4. Stereoselectivity of Hydride Reducing Agent

Reducing agent					
	% axial	% axial	% axial	% endo	% exo
NaBH_4	20 ^b	25 ^c	58 ^c	86 ^d	86 ^d

¹²¹. A. Krief and D. Surleraux, *Synlett*, 273 (1991).

Similarly, $\text{NaBH}_4\text{-CeCl}_3$ reverses the stereochemistry relative to NaBH_4 in the bicyclic ketone **12**.¹²²

Thus, $\text{NaBH}_4\text{-CeCl}_3$ tends to give the *more stable* alcohol, but the origin of this stereoselectivity does not seem to have been established. It is thought that these reductions proceed through alkoxyborohydrides.¹²³ It is likely that equilibration occurs by reversible hydride transfer.

5.3.2.2. Acyclic Ketones. The stereochemistry of the reduction of acyclic aldehydes and ketones is a function of the substitution on the adjacent carbon atom and can be predicted on the basis of the Felkin conformational model of the TS,⁶³ which is based on a combination of steric and stereoelectronic effects.

From a purely steric standpoint, minimal steric interaction with the groups L and M by approaching from the direction of the smallest substituent is favorable. The stereoelectronic effect involves the interaction between the approaching hydride ion and the LUMO of the carbonyl group. This orbital, which accepts the electrons of the incoming nucleophile, is stabilized when the group L is perpendicular to the plane of the carbonyl group.¹²⁴ This conformation permits a favorable interaction between the LUMO and the antibonding σ^* orbital associated with the C–L bond.

In the case of α -substituted phenyl ketones, the order of stereoselectivity is $\text{C}\equiv\text{CH} > \text{CH}=\text{CH}_2 > \text{CH}_2\text{CH}_3$.¹²⁵ These results indicate a stereoelectronic as well as a steric

Steric factors arising from groups that are more remote from the center undergoing reduction can also influence the stereochemical course of reduction. Such steric factors are magnified by use of bulky reducing agents. For example, a 4.5:1 preference for stereoisomer **14** over **15** is achieved by using the trialkylborohydride **13** as the reducing agent in the reduction of a prostaglandin intermediate.¹²⁶

5.3.2.3. Chelation Control. The stereoselectivity of reduction of carbonyl groups can be controlled by chelation when there is a nearby donor substituent. In the presence of such a group, specific complexation among the substituent, the carbonyl oxygen, and the Lewis acid can establish a preferred conformation for the reactant. Usually hydride is then delivered from the less sterically hindered face of the chelate so the hydroxy group is *anti* to the chelating substituent.

α -Hydroxy¹²⁷ and α -alkoxyketones¹²⁸ are reduced to *anti* 1,2-diols by $\text{Zn}(\text{BH}_4)_2$ through a chelated TS. This stereoselectivity is consistent with the preference for TS **F**

¹²⁶ E. J. Corey, S. M. Albonico, U. Koelliker, T. K. Schaaf, and R. K. Varma, *J. Am. Chem. Soc.*, **93**, 1491 (1971).

over **G**. The stereoselectivity increases with the bulk of substituent R^2 . LiAlH_4 shows the same trend, but is not as stereoselective.

R^1	R^2	$\text{Zn}(\text{BH}_4)_2$ <i>anti:syn</i>	LiAlH_4 <i>anti:syn</i>
$n\text{-C}_5\text{H}_{11}$	CH_3	77:23	64:36
CH_3	$n\text{-C}_5\text{H}_{11}$	85:15	70:30
$i\text{-C}_3\text{H}_7$	CH_3	85:15	58:42
CH_3	$i\text{-C}_3\text{H}_7$	96:4	73:27
Ph	CH_3	98:2	87:13
CH_3	Ph	90:10	80:20

Reduction of β -hydroxy ketones through chelated TSs favors *syn*-1,3-diols. Boron chelates have been exploited to achieve this stereoselectivity.¹²⁹ One procedure involves in situ generation of diethylmethoxyboron, which then forms a chelate with the β -hydroxyketone. Reduction with NaBH_4 leads to the *syn*-diol.¹³⁰

This procedure was used in the synthesis of the cholesterol-reducing drug Iescol.¹³¹ The diethylmethoxyboron can be prepared in situ from triethylboron and one equivalent of methanol.

Syn-1,3-diols can be obtained from β -hydroxyketones using LiI-LiAlH_4 at low temperatures.¹³² β -Hydroxyketones also give primarily *syn*-1,3-diols when

chelates prepared with BCl_3 are reduced with quaternary ammonium salts of BH_4^- or BH_3CN^- .¹³³

Similar results are obtained with β -methoxyketones using TiCl_4 as the chelating reagent.¹³⁴

The effect of the steric bulk of the hydride reducing agent has been examined in the case of 3-benzyloxy-2-butanone.¹³⁵ The ratio of chelation-controlled product increased with the steric bulk of the reductant. This is presumably due to amplification of the steric effect of the methyl group in the chelated TS as the reductant becomes more sterically demanding. In these reactions, the degree of chelation control was also enhanced by use of CH_2Cl_2 as a cosolvent.

A survey of several of alkylborohydrides found that LiBu_3BH in ether-pentane gave the best ratio of chelation-controlled reduction products from α - and β -alkoxy ketones.¹³⁴ In this case, the Li^+ cation acts as the Lewis acid. The alkylborohydrides provide an added increment of steric discrimination.

Tetramethylammonium triacetoxymethylborohydride gives *anti*-1,3-diols from β -hydroxy ketones.¹³⁶ These reactions are thought to occur by a rapid exchange that introduces the hydroxy group as a boron ligand.

¹³³. C. R. Sarko, S. E. Collibee, A. L. Knorr, and M. DiMare, *J. Org. Chem.*, **61**, 868 (1996).

¹³⁴. C. R. Sarko, I. C. Guch, and M. DiMare, *J. Org. Chem.*, **59**, 705 (1994); G. Bartoli, M. C. Bellucci, M. Bosco, R. Dalpozzo, E. Marcantoni, and L. Sambri, *Tetrahedron Lett.*, **40**, 2845 (1999).

¹³⁵. A.-M. Faucher, C. Brochu, S. R. Landry, I. Duchesne, S. Hantos, A. Roy, A. Myles, and C. Legault, *Tetrahedron Lett.*, **39**, 8425 (1998).

¹³⁶. D. A. Evans, K. T. Chapman, and E. M. Carreira, *J. Am. Chem. Soc.*, **110**, 3560 (1988).

Similarly, cyclic ketones **16** and **17** both give the *trans*-diol, as anticipated for intramolecular delivery of hydride. In the case of the equatorial alcohol, the reaction must occur through a nonchair conformer.

In 2-hydroxy-2,4-dimethylcyclohexanone there is a strong preference for equatorial attack by LiAlH_4 , NaBH_4 , and $\text{Zn}(\text{BH}_4)_2$.¹³⁷ In the case of the less conformationally biased 2-hydroxy-2-methylcyclohexanone, stereoselectivity is much weaker for these reductants, but is high for $\text{NaB}(\text{OAc})_3\text{H}$. These results are attributed to prior complexation of the hydride at the hydroxy group with intramolecular delivery of hydride, leading to *anti*-diol. A 3-hydroxy substituent had a much weaker effect, except with $\text{NaB}(\text{OAc})_3\text{H}$. This reagent presumably reacts more rapidly with hydroxy groups because of the greater lability of the acetoxo substituents, and in this case the reagent becomes a better hydride donor by replacing acetoxo with an alkoxide.

% <i>anti</i> -diol		% <i>anti</i> -diol	
NaBH_4	100	NaBH_4	57
LiAlH_4	100	LiAlH_4	74
$\text{Zn}(\text{BH}_4)_2$	100	$\text{Zn}(\text{BH}_4)_2$	75
$\text{NaB}(\text{OAc})_3\text{H}$	100	$\text{NaB}(\text{OAc})_3\text{H}$	97

Similar studies were carried out with methoxycyclohexanones.¹³⁸ 3-Methoxy groups showed no evidence of chelation effects with these reagents and the 2-methoxy group showed an effect only with $\text{Zn}(\text{BH}_4)_2$. This supports the suggestion that the effect of the hydroxy groups operates through deprotonated alkoxide complexes.

Chelation effects also come into play in the reduction of α,β -epoxyketones. Both CaCl_2 and LaCl_3 lead to enhanced *anti* stereoselectivity.¹³⁹ The same stereoselectivity is observed with CeCl_3 and with $\text{Zn}(\text{BH}_4)_2$.¹⁴⁰

β -Ketosulfoxides are subject to chelation control when reduced by DiBAIH in the presence of ZnCl₂.¹⁴¹ This allows the use of chirality of the sulfoxide group to control the stereochemistry at the ketone carbonyl.

5.3.3. Enantioselective Reduction of Carbonyl Compounds

5.3.3.1. Reduction with Chiral Boranes. The reduction of an unsymmetrical ketone creates a new stereogenic center. Owing to the importance of hydroxy groups both in synthesis and in the properties of molecules, including biological activity, there has been a great deal of effort directed toward enantioselective reduction of ketones. One approach is to use chiral borohydride reagents.¹⁴² Boranes derived from chiral alkenes can be converted to alkylborohydrides, and several such reagents are commercially available.¹⁴³

Chloroboranes have also been found useful for enantioselective reduction. Di-(isopinocampheyl)chloroborane,¹⁴⁴ (Ipc)₂BCl, and *t*-butyl(isopinocampheyl)

chloroborane¹⁴⁵ achieve high enantioselectivity for aryl and branched dialkyl ketones. Di-(iso-2-ethylapopinocampheyl)chloroborane,¹⁴⁶ (Eap)₂BCl, shows good enantioselectivity for a wider range of alcohols.

For example, (Ipc)₂BCl was found to be an advantageous in the enantioselective reduction in the large-scale preparation of L-699,392, a specific leukotriene antagonist of interest in the treatment of asthma.¹⁴⁷

These reagents react through cyclic TSs and regenerate an alkene.

Table 5.5 gives some typical results for enantioselective reduction of ketones by alkylborohydrides and chloroboranes.

5.3.3.2. Catalytic Enantioselective Reduction of Ketones. An even more efficient approach to enantioselective reduction is to use a chiral catalyst. One of the most developed is the oxazaborolidine **18**, which is derived from the amino acid proline.¹⁴⁸ The enantiomer is also available. These catalysts are called the *CBS-oxazaborolidines*.

A catalytic amount (5–20 mol %) of the reagent, along with BH₃ as the reductant, can reduce ketones such as acetophenone and pinacolone in more than 95% e.e. An adduct of borane and **18** is the active reductant. This adduct can be prepared, stored,

and used as a stoichiometric reagent if so desired.¹⁴⁹ The catalytic cycle depends on dissociation of the reduced product.

The corresponding *N*-butyloxazaborolidine is also frequently used as a catalyst. The enantioselectivity and reactivity of these catalysts can be modified by changes in substituent groups to optimize selectivity toward a particular ketone.¹⁵⁰ Catecholborane can also be used as the reductant.¹⁵¹

Both mechanistic and computational studies have been used to explore the catalytic process. A crystal structure of the catalysts is available (Figure 5.7).¹⁵² The

orientation of the ketone is dictated by the phenyl groups and the relatively rigid geometry of the ring system. The enantioselectivity in these reductions is proposed to arise from a chairlike TS in which the governing steric interaction is with the alkyl substituent on boron.^{153,154} There are experimental data indicating that the steric demand of the boron substituent influences enantioselectivity.¹⁵⁴

There have been *ab initio* studies of the transition structure using several model catalysts and calculations at the HF/3-21G, HF/6-31G(*d*), and MP2/6-31G(*d*) levels.¹⁵⁵ The enantioselectivity is attributed to the preference for an *exo* rather than an *endo* approach of the ketone, as shown in Figure 5.8.

According to B3LYP/6-31G* computations of the intermediates and TSs, there are no large barriers to the reaction and it is strongly exothermic.¹⁵⁶ Measured E_a values are around 10 kcal/mol.¹⁵⁷ The complexation of borane to the catalyst shifts electron density from nitrogen to boron and enhances the nucleophilicity of the hydride. The

complexation also diminishes the N–B delocalization present in the oxazaborolidine ring, with the bond length increasing from 1.410 to 1.498 Å, according to the computations. The computed structural parameters are close to those found by crystallography.

Scheme 5.6 shows some examples of enantioselective reduction of ketones using CBS-oxazaborolidine catalysts. The reaction in Entry 1 was carried out in the course of synthesis of a potential drug candidate. Entry 2 employs the catalyst to achieve stereoselective reduction at the C(15) center in a prostaglandin precursor. Entries 3 and 4 report high enantioselectivity in the reduction of cyclic ketones. Entries 5 and 6 are cases of acyclic ketones with adjacent functionality and are reduced with high enantioselectivity. Entries 7 and 8 are applications of the reaction to aromatic ketones done on a relatively large scale in the course of drug development. Entry 7 used an indane-derived aminoalcohol as the oxazaborolidine precursor, whereas the procedure in Entry 8 involves in situ generation of the CBS catalyst. Entries 9 to 14 show other examples of the reaction that were carried out in the course of multistage syntheses of complex molecules.

Enantioselective 1,4-reduction of enones can be done using a copper-BINAP catalyst in conjunction with silicon hydride donors.¹⁵⁸ Polymethylhydrosilane (PMHS) is one reductants that is used.

The reduction can also be effected with diphenylsilane and the intermediate silyl enol ethers can be alkylated in a tandem process.¹⁵⁹

When necessary, the *trans*:*cis* ratio can be improved by base-catalyzed equilibration.

5.3.4. Reduction of Other Functional Groups by Hydride Donors

Although reductions of the common carbonyl and carboxylic acid derivatives are the most prevalent uses of hydride donors, these reagents can reduce a number of other groups in ways that are of synthetic utility. Halogen and sulfonate leaving groups can undergo replacement by hydride. Both aluminum and boron hydrides exhibit this reactivity, and lithium trialkylborohydrides are especially reactive.¹⁶⁰ The reduction is particularly rapid and efficient in polar aprotic solvents such as DMSO, DMF, and HMPA. Table 5.6 gives some indication of the reaction conditions. The normal factors in susceptibility to nucleophilic attack govern reactivity with $\text{I} > \text{Br} > \text{Cl}$ being the order in terms of the leaving group and $\text{benzyl} \sim \text{allyl} > \text{primary} > \text{secondary} > \text{tertiary}$ in terms of the substitution site.¹⁶¹ For primary alkyl groups, it is likely that the reaction proceeds by an $\text{S}_{\text{N}}2$ mechanism. However, the range of halides that can be reduced includes aryl halides and bridgehead halides, which cannot react by the $\text{S}_{\text{N}}2$ mechanism.¹⁶² The loss of stereochemical integrity in the reduction of vinyl halides suggests the involvement of radical intermediates.¹⁶³ Formation and subsequent

SECTION 5.3

Group III
Hydride-Donor Reagents

dissociation of a radical anion by one-electron transfer is a likely mechanism for reductive dehalogenation of compounds that cannot react by an $\text{S}_{\text{N}}2$ mechanism.

One experimental test for the involvement of radical intermediates is to study 5-hexenyl systems and look for the characteristic cyclization to cyclopentane derivatives (see Part A, Section 11.2.3). When 5-hexenyl bromide or iodide reacts with LiAlH_4 , no cyclization products are observed. However, the more hindered 2,2-dimethyl-5-hexenyl iodide gives mainly cyclic product.¹⁶⁴

Some cyclization also occurs with the bromide, but not with the chloride or the tosylate. The secondary iodide, 6-iodo-1-heptene, gives a mixture of cyclic and acyclic product in THF.¹⁶⁵

¹⁶⁴. E. C. Ashby, R. N. DePriest, A. B. Goel, B. Wenderoth, and T. N. Pham, *J. Org. Chem.*, **49**, 3545 (1984).

¹⁶⁵. E. C. Ashby, T. N. Pham, and A. Amrollah-Madjadabadi, *J. Org. Chem.*, **56**, 1596 (1991).

The occurrence of a radical intermediate is also indicated in the reduction of 2-octyl iodide by LiAlD_4 since, in contrast to the chloride or bromide, extensive racemization accompanies reduction.

The presence of transition metal ions has a catalytic effect on reduction of halides and tosylates by LiAlH_4 .¹⁶⁶ Various “copper hydride” reducing agents are effective for removal of halide and tosylate groups.¹⁶⁷ The primary synthetic value of these reductions is for the removal of a hydroxy function after conversion to a halide or tosylate.

Epoxides are converted to alcohols by LiAlH_4 in a reaction that occurs by nucleophilic attack, and hydride addition at the less hindered carbon of the epoxide is usually observed.

Cyclohexene epoxides are preferentially reduced by an axial approach by the nucleophile.¹⁶⁸

Lithium triethylborohydride is a superior reagent for the reduction of epoxides that are relatively unreactive or prone to rearrangement.¹⁶⁹

Alkynes are reduced to *E*-alkenes by LiAlH_4 .¹⁷⁰ This stereochemistry is complementary to that of partial hydrogenation, which gives *Z*-isomers. Alkyne reduction by LiAlH_4 is greatly accelerated by a nearby hydroxy group. Typically, propargylic alcohols react in ether or tetrahydrofuran over a period of several hours,¹⁷¹ whereas forcing conditions are required for isolated triple bonds.¹⁷² This is presumably the result of coordination of the hydroxy group at aluminum and formation of a cyclic intermediate. The involvement of intramolecular Al–H addition has been demonstrated by use of LiAlD_4 as the reductant. When reduction by LiAlD_4 is followed by quenching with normal water, propargylic alcohol gives *Z*-3-²H-prop-2-enol. Quenching with D_2O gives 2-²H-3-²H-prop-2-enol.¹⁷³

The efficiency and stereospecificity of reduction is improved by using a 1:2 mixture of $\text{LiAlH}_4\text{-NaOCH}_3$ as the reducing agent.¹⁷⁴ The mechanistic basis of this effect has not been explored in detail.

Scheme 5.7 illustrates these and other applications of the hydride donors. Entries 1 and 2 are examples of reduction of alkyl halides, whereas Entry 3 shows removal of an aromatic halogen. Entries 4 to 6 are sulfonate displacements, with the last example using a copper hydride reagent. Entry 7 is an epoxide ring opening. Entries 8 and 9 illustrate the difference in ease of reduction of alkynes with and without hydroxy participation.

5.4. Group IV Hydride Donors

5.4.1. Reactions Involving Silicon Hydrides

Both Si-H and C-H compounds can function as hydride donors under certain circumstances. The silicon-hydrogen bond is capable of transferring a hydride to carbocations. Alcohols that can be ionized in trifluoroacetic acid are reduced to hydrocarbons in the presence of a silane.

Ref. 175

Aromatic aldehydes and ketones are reduced to alkylaromatics under similar conditions through reactions involving benzylic cations.¹⁷⁶

Aryl ketones are also reduced with triethylsilane and TiCl_4 . This method can be used to prepare γ -arylaminoacids.¹⁷⁷

Aliphatic ketones can be reduced to hydrocarbons by triethylsilane and gaseous BF_3 .¹⁷⁸ The BF_3 is a sufficiently strong Lewis acid to promote formation of a carbocation from the intermediate alcohol.

A combination of Friedel-Crafts alkylation and reduction can be achieved using InCl_3 and chlorodimethylsilane. The Lewis acid presumably promotes both the Friedel-Craft reaction and the subsequent reduction.¹⁷⁹

There are several procedures for reductive condensation of silyl ethers with carbonyl compounds to form ethers. One method uses TMSOTf as the catalyst.¹⁸⁰

A number of related procedures have been developed. For example, TMSI can be used.¹⁸¹

The trimethylsilyl group can be replaced by a dialkylsilyloxy group, in which case the silyl ether serves as the hydride donor.

Ref. 183

These reactions presumably proceed by catalytic cycles in which the carbonyl component is silylated. The silyl ether can then act as a nucleophile, and an oxonium ion is generated by elimination of a disilyl ether. The reduction of the oxonium ion regenerates the silyl cation, which can continue the catalytic cycle.

Various other kinds of Lewis acids can also promote the reaction. For example, $\text{Cu}(\text{OTf})_2$ and Et_3SiH have been used to prepare a number of benzyl and alkyl ethers.¹⁸⁴

The reductive condensation can also be carried out using BiBr_3 and Et_3SiH . The active catalyst under these conditions is Et_3SiBr , which is generated in situ.¹⁸⁵

Reduction of ketones to triphenylsilyl ethers is effected by the unique Lewis acid perfluorotriphenylborane. Mechanistic and kinetic studies have provided considerable insight into the mechanism of this reaction.¹⁸⁶ The salient conclusion is that the hydride is delivered from a borohydride ion, not directly from the silane. Although the borane forms a Lewis acid-base complex with the ketone, its key function is in delivery of the hydride.

Copper-catalyzed systems have been developed that reduce ketones directly to silyl ethers. The reactions involve chiral biphenyl diphosphine type ligands and silane or siloxane hydride donors.¹⁸⁷

The reactions proceed with an e.e. of about 80% when the enantiopure ligand is used. Similar conditions using poly[oxy(methylsilylene)] (PMHS) as the hydride donor lead to reduction of aryl ketones with up to 98% e.e.¹⁸⁸

5.4.2. Hydride Transfer from Carbon

There are also reactions in which hydride is transferred from carbon. The carbon-hydrogen bond has little intrinsic tendency to act as a hydride donor, so especially favorable circumstances are required to promote this reactivity. Frequently these reactions proceed through a cyclic TS in which a new C–H bond is formed simultaneously with the C–H cleavage. Hydride transfer is facilitated by high electron density at the carbon atom. Aluminum alkoxides catalyze transfer of hydride from an alcohol to a ketone. This is generally an equilibrium process and the reaction can be driven to completion if the ketone is removed from the system, by, e.g., distillation, in a process known as the *Meerwein-Ponndorff-Verley reduction*.¹⁸⁹ The reverse reaction in which the ketone is used in excess is called the *Oppenauer oxidation*.

The reaction proceeds via a cyclic TS involving coordination of both the alcohol and ketone oxygens to the aluminum. Computational (DFT) and isotope effect studies are consistent with the cyclic mechanism.¹⁹⁰ Hydride donation usually takes place from

the less hindered face of the carbonyl group.¹⁹¹ However, these conditions frequently promote equilibration of the alcohol stereoisomers.

Recently, enantioselective procedures involving chiral catalysts have been developed. The combination of BINOL and $\text{Al}(\text{CH}_3)_3$ can achieve 80% e.e. in the reduction of acetophenone.¹⁹² Compound **J** is also an effective catalyst.¹⁹³

Certain lanthanide alkoxides, such as *t*-BuOSmI₂, have also been found to catalyze hydride exchange between alcohols and ketones.¹⁹⁴ Isopropanol can serve as the reducing agent for aldehydes and ketones that are thermodynamically better hydride acceptors than acetone.

Samarium metal in isopropanol also achieves reduction.¹⁹⁵ Like the Meerwein-Ponndorf-Verley procedure, these conditions are believed to be under thermodynamic control and the more stable stereoisomer is the main product.¹⁹⁶

Another reduction process, catalyzed by iridium chloride, is characterized by very high axial:equatorial product ratios for cyclohexanones and apparently involves hydride transfer from isopropanol.¹⁹⁷

Formic acid can also act as a donor of hydrogen, and the driving force in this case is the formation of carbon dioxide. A useful application is the Clark-Eschweiler

reductive methylation of amines, in which heating a primary or secondary amine with formaldehyde and formic acid results in complete methylation to the tertiary amine.¹⁹⁸

The hydride acceptor is the iminium ion that results from condensation of the amine with formaldehyde.

5.5. Reduction Reactions Involving Hydrogen Atom Donors

Reduction by hydrogen atom donors involves free radical intermediates and usually proceeds by chain mechanisms. Tri-*n*-butylstannane is the most prominent example of this type of reducing agent. Other synthetically useful hydrogen atom donors include hypophosphorous acid, dialkyl phosphites, and *tris*-(trimethylsilyl)silane. The processes that have found most synthetic application are reductive replacement of halogen and various types of thiono esters.

Tri-*n*-butylstannane is able to reductively replace halogen by hydrogen. Mechanistic studies indicate a free radical chain mechanism.¹⁹⁹ The order of reactivity for the halides is $\text{RI} > \text{RBr} > \text{RCl} > \text{RF}$, which reflects the relative ease of the halogen atom abstraction.²⁰⁰

Scheme 5.8 gives several examples of dehalogenation using tri-*n*-butylstannane. Entries 1 and 2 are examples from the early studies of this method. Entries 3 and 4 illustrate selective dehalogenation of polyhalogenated compounds. The stabilizing effect of the remaining halogen on the radical intermediate facilitates partial dehalogenation. These reactions also demonstrate stereoselectivity. In Entry 3, the stereochemical preference is for hydrogen abstraction from the more accessible face of the radical intermediate. Entry 4 shows retention of configuration at the fluorocyclopropyl carbon. (The stereoisomeric compound also reacts with retention of configuration.) This result indicates that hydrogen abstraction is faster than inversion for these cyclopropyl radicals (see Part A, Section 11.1.5).

A procedure that is catalytic in Bu_3SnH and uses NaBH_4 as the stoichiometric reagent has been developed.²⁰¹ This method has advantages in the isolation and purification of product. Entry 5 is an example of this procedure. The reaction was carried

out under illumination to provide for chain initiation, and the reactant was prepared by an iodolactonization reaction. The sequence iodolactonization-dehalogenation is frequently used in the synthesis of five-membered lactones. Entry 6 illustrates the use of dehalogenation with deuterium incorporation. The addition of the fluoride salt facilitates workup by precipitation of tin by-products.

Hypophosphorous acid has been used as a hydrogen atom donor in the dehalogenation of nucleosides.²⁰²

²⁰² S. Takamatsu, S. Katayama, N. Hirose, M. Naito, and K. Izawa, *Tetrahedron Lett.*, **42**, 7605 (2001).

Tri-*n*-butyltin hydride also serves as a hydrogen atom donor in radical-mediated methods for reductive deoxygenation of alcohols via thiono esters.²⁰³ The alcohol is converted to a thiocarbonyl derivative. These thiono esters undergo a radical reaction with tri-*n*-butyltin hydride. The resulting radicals fragment to give the alkyl radical, and the chain is propagated by hydrogen atom abstraction.

This procedure gives good yields from secondary alcohols and by appropriate adjustment of conditions can also be adapted to primary alcohols.²⁰⁴

Owing to the expense, toxicity, and purification problems associated with use of stoichiometric amounts of tin hydrides, there has been interest in finding other hydrogen atom donors.²⁰⁵ The trialkylboron-oxygen system for radical generation (see Part A, Section 11.1.4) has been used with *tris*-(trimethylsilyl)silane or diphenylsilane as a hydrogen donor.²⁰⁶

Chain reaction mechanism

The alcohol derivatives that have been successfully deoxygenated include thiocarbonates and xanthates.²⁰⁷ Peroxides can be used as initiators.²⁰⁸

Scheme 5.9 illustrates some of the conditions that have been developed for the reductive deoxygenation of alcohols. Entries 1 to 4 illustrate the most commonly used methods for generation of thiono esters and their reduction by tri-*n*-butylstannane. These include formation of thiono carbonates (Entry 1), xanthates (Entry 2), and thiono imidazolides (Entries 3 and 4). Entry 5 is an example of use of dimethyl phosphite as the hydrogen donor. Entry 6 uses *tris*-(trimethylsilyl)silane as the hydrogen atom donor.

Another group of synthetically useful reductions employs a metal as the reducing agent. The organic reactant under these conditions accepts one or more electrons from the metal. The subsequent course of the reaction depends on the structure of the

reactant and reaction conditions. Three broad types of reactions can be recognized and these are discussed separately. They include reactions in which the overall change involves: (a) net addition of hydrogen, (b) reductive removal of a functional group, and (c) formation of carbon-carbon bonds.

5.6.1. Addition of Hydrogen

5.6.1.1. Reduction of Ketones and Enones. Although the method has been supplanted for synthetic purposes by hydride donors, the reduction of ketones to alcohols in ammonia or alcohols provides mechanistic insight into dissolving-metal reductions. The outcome of the reaction of ketones with metal reductants is determined by the fate of the initial ketyl radical formed by a single-electron transfer. The radical intermediate, depending on its structure and the reaction medium, may be protonated, disproportionate, or dimerize.²⁰⁹ In hydroxylic solvents such as liquid ammonia or in the presence of an alcohol, the protonation process dominates over dimerization. Net reduction can also occur by a disproportionation process. As is discussed in Section 5.6.3, dimerization can become the dominant process under conditions in which protonation does not occur rapidly.

α, β -Unsaturated carbonyl compounds are cleanly reduced to the enolate of the corresponding saturated ketone on reduction with lithium in ammonia.²¹⁰ Usually an alcohol is added to the reduction solution to serve as the proton source.

As noted in Chapter 1, this is one of the best methods for generating a specific enolate of a ketone. The enolate generated by conjugate reduction can undergo the characteristic alkylation and addition reactions that are discussed in Chapters 1 and 2. When this is the objective of the reduction, it is important to use only one equivalent of the proton donor. Ammonia, being a weaker acid than an aliphatic ketone, does

²⁰⁹ V. Rautenstrauch and M. Geoffroy, *J. Am. Chem. Soc.*, **99**, 6280 (1977); J. W. Huffman and W. W. McWhorter, *J. Org. Chem.*, **44**, 594 (1979); J. W. Huffman, P. C. Desai, and J. E. LaPrade, *J. Org. Chem.*, **48**, 1474 (1983).

²¹⁰ D. Caine, *Org. React.*, **23**, 1 (1976).

not act as a proton donor toward an enolate, and the enolate remains available for subsequent reaction, as in the tandem alkylations shown below. If the saturated ketone is the desired product, the enolate is protonated either by use of excess proton donor during the reduction or on workup.

Ref. 211

Ref. 212

The stereochemistry of conjugate reduction is established by the proton transfer to the β -carbon. In the well-studied case of $\Delta^{1,9}$ -2-octalones, the ring junction is usually *trans*.²¹³

The stereochemistry is controlled by a stereoelectronic preference for protonation perpendicular to the enolate system and, given that this requirement is met, the stereochemistry normally corresponds to protonation of the most stable conformation of the dianion intermediate from its least hindered side.

5.6.1.2. Dissolving-Metal Reduction of Aromatic Compounds and Alkynes. Dissolving-metal systems constitute the most general method for partial reduction of aromatic rings. The reaction is called the *Birch reduction*,²¹⁴ and the usual reducing medium is lithium or sodium in liquid ammonia. An alcohol is usually added to serve as a proton source. The reaction occurs by two successive electron transfer/protonation steps.

²¹⁴ A. J. Birch and G. Subba Rao, *Adv. Org. Chem.*, **8**, 1 (1972); R. G. Harvey, *Synthesis*, 161 (1980); J. M. Hook and L. N. Mander, *Nat. Prod. Rep.*, **3**, 35 (1986); P. W. Rabideau, *Tetrahedron*, **45**, 1599 (1989); A. J. Birch, *Pure Appl. Chem.*, **68**, 553 (1996).

The isolated double bonds in the dihydro product are much less easily reduced than the conjugated ring, so the reduction stops at the dihydro stage. Alkyl and alkoxy aromatics, phenols, and benzoate anions are the most useful reactants for Birch reduction. In aromatic ketones and nitro compounds, the substituents are reduced in preference to the aromatic ring. Substituents also govern the position of protonation. Alkyl and alkoxy aromatics normally give the 2,5-dihydro derivative. Benzoate anions give 1,4-dihydro derivatives.

The structure of the products is determined by the site of protonation of the radical anion intermediate formed after the first electron transfer step. In general, ERG substituents favor protonation at the *ortho* position, whereas EWGs favor protonation at the *para* position.²¹⁵ Addition of a second electron gives a pentadienyl anion, which is protonated at the center carbon. As a result, 2,5-dihydro products are formed with alkyl or alkoxy substituents and 1,4-products are formed from EWG substituents. The preference for protonation of the central carbon of the pentadienyl anion is believed to be the result of the greater 1,2 and 4,5 bond order and a higher concentration of negative charge at C(3).²¹⁶ The reduction of methoxybenzenes is of importance in the synthesis of cyclohexenones via hydrolysis of the intermediate enol ethers.

The anionic intermediates formed in Birch reductions can be used in tandem alkylation reactions.

 f. M. D. Soffer, M. P. Bellis, H. E. Gellerson, and R. A. Stewart, *Org. Synth.*, **IV**, 903 (1963).

Scheme 5.10 lists some examples of the use of the Birch reduction. Entries 1 and 2 illustrate the usual regioselectivity for alkoxy aromatics and for benzoic acid. Entry 3 uses an alkylamine as the solvent. In the case cited, the yield was much better than that obtained using ammonia. Entry 4 illustrates the preparation of a cyclohex-3-enone via the Birch reduction route. Entries 5 and 6 show an interesting contrast in the regioselectivity of naphthalene derivatives. The selective reduction of the unsubstituted ring may reflect the more difficult reduction of the ring having a deprotonated oxy substituent. On the other hand, empirical evidence indicates that ERG substituents in the 2-position direct reduction to the substituted ring.²¹⁹ The basis of this directive effect does not seem to have been developed in modern electronic terms.

²¹⁹ M. D. Soffer, R. A. Stewart, J. C. Cavagnol, H. E. Gellerson, and E. A. Bowler, *J. Am. Chem. Soc.*, **72**, 3704 (1950).

Reduction of acetylenes can be done with sodium in ammonia,²²⁰ lithium in low molecular weight amines,²²¹ or sodium in HMPA containing *t*-butanol as a proton source,²²² all of which lead to the *E*-alkene. The reaction is assumed to involve successive electron transfer and protonation steps.

5.6.2. Reductive Removal of Functional Groups

The reductive removal of halogen can be accomplished with lithium or sodium. Tetrahydrofuran containing *t*-butanol is a useful reaction medium. Good results have also been achieved with polyhalogenated compounds by using sodium in ethanol.

Ref. 223

An important synthetic application of this reaction is in dehalogenation of dichloro- and dibromocyclopropanes. The dihalocyclopropanes are accessible via carbene addition reactions (see Section 10.2.3). Reductive dehalogenation can also be used to introduce deuterium at a specific site. The mechanism of the reaction involves electron transfer to form a radical anion, which then fragments with loss of a halide ion. The resulting radical is reduced to a carbanion by a second electron transfer and subsequently protonated.

Phosphate groups can also be removed by dissolving-metal reduction. Reductive removal of vinyl phosphate groups is one method for conversion of a carbonyl compound to an alkene.²²⁴ (See Section 5.7.2 for other methods.) The required vinyl phosphate esters are obtained by phosphorylation of the enolate with diethyl phosphorochloridate or *N,N,N',N'*-tetramethyldiamidophosphorochloridate.²²⁵

Ketones can also be reduced to alkenes via enol triflates. The use of $\text{Pd}(\text{OAc})_2$ and triphenylphosphine as the catalyst and tertiary amines as the hydrogen donors is effective.²²⁶

Ref. 227

Reductive removal of oxygen from aromatic rings can also be achieved by reductive cleavage of aryl diethyl phosphate esters.

Ref. 228

There are also examples in which phosphate esters of saturated alcohols are reductively deoxygenated.²²⁹ Mechanistic studies of the cleavage of aryl dialkyl phosphates have indicated that the crucial C—O bond cleavage occurs after transfer of two electrons.²³⁰

For preparative purposes, titanium metal can be used in place of sodium or lithium in liquid ammonia for both the vinyl phosphate²³¹ and aryl phosphate²³² cleavages. The titanium metal is generated in situ from TiCl_3 by reduction with potassium metal in tetrahydrofuran.

Scheme 5.11 shows some examples of these reductive reactions. Entry 1 is an example of conditions that have been applied to both alkyl and aryl halides. The reaction presumably proceeds through formation of a Grignard reagent, which then undergoes protonolysis. Entries 2 and 3 are cases of the dehalogenation of polyhalogenated compounds by sodium in *t*-butanol. Entry 4 illustrates conditions that were found useful for monodehalogenation of dibromo- and dichlorocyclopropanes. This method is not very stereoselective. In the example given, the ratio of *cis:trans* product was 1.2:1. Entries 5 to 7 are cases of dissolving-metal reduction of vinyl and aryl phosphates.

Both metallic zinc and aluminum amalgam are milder reducing agents than the alkali metals. These reductants selectively remove oxygen and sulfur functional groups α to carbonyl groups. The mechanistic picture that seems most generally applicable is a net two-electron reduction with expulsion of the oxygen or sulfur substituent as an anion. The reaction must be a concerted process, because the isolated functional groups are not reduced under these conditions.

Another useful reagent for reduction of α -acetoxyketones and similar compounds is samarium diiodide.²³³ SmI_2 is a strong one-electron reducing agent, and it is believed that the reductive elimination occurs after a net two-electron reduction of the carbonyl group.

These conditions were used, for example, in the preparation of the anticancer compound 10-deacetoxytaxol.

Ref. 234

Scheme 5.12 gives some examples of the reductive removal of functional groups adjacent to carbonyl groups. Entry 1 is an application of this reaction as it was used in an early steroid synthesis. The reaction in Entry 2 utilizes calcium in ammonia for the reduction. The reaction in Entry 3 converts the acyloin derived from dimethyl decanedecarboxylate into cyclodecanone. In the reaction in Entry 4, a sulfonate group is removed. In Entry 5 an epoxide is opened using aluminum amalgam, and in Entry 6 a lactone ring is opened. The latter reaction was part of a synthetic sequence in which the lactone intermediate was used to establish the stereochemistry of the acyclic product. The reaction in Entry 7 removes a sulfinyl group. Keto sulfoxides can be obtained by acylation of the anion of dimethylsulfoxide, so this reaction constitutes a general route to ketones (see Section 2.3.2). The reaction in Entry 8 is a *vinyllogous* version of the reduction. The reductant in Entries 9 and 10 is SmI_2 . In Entry 9, the 2-phenylcyclohexyloxy group that is removed was used earlier in the synthesis as a chiral auxiliary. Samarium diiodide is useful for deacetoxylation or dehydroxylation of α -oxygenated lactones derived from carbohydrates (Entry 10).²³⁵ The reaction is also applicable to protected hydroxy groups, such as in acetonides. The reactions in Scheme 5.12 include quite a broad range of reductable groups, including some (e.g., ether) that are modest leaving groups.

5.6.3. Reductive Coupling of Carbonyl Compounds

As reductions by metals often occur by one-electron transfers, radicals are involved as intermediates. When the reaction conditions are adjusted so that coupling competes favorably with other processes, the formation of a carbon-carbon bond can occur. The reductive coupling of acetone to 2,3-dimethylbutane-2,3-diol (pinacol) is an example of such a reaction.

Ref. 236

Reduced forms of titanium are currently the most versatile and dependable reagents for reductive coupling of carbonyl compounds. These reagents are collectively referred to as *low-valent titanium*. Either diols or alkenes can be formed, depending on the conditions.²³⁷ Several different procedures have evolved for titanium-mediated coupling. One procedure involves prereduction of TiCl_3 with strong reducing agents such as LiAlH_4 ,²³⁸ potassium on graphite (C_8K),²³⁹ or Na-naphthalenide.^{240b} The reductant prepared in this way is quite effective at coupling reactants with several oxygen substituents.

Another particularly reactive form of titanium is generated by including 0.25 equivalent of I_2 . This reagent permits low-temperature reductive deoxygenation to alkenes.²⁴¹

Titanium metal is also activated by TMS-Cl.²⁴² These conditions were used in a number of dimerizations and cyclizations, including the formation of a 36-membered ring.

Another process that is widely used involves reduction by Zn-Cu couple. This reagent is especially reliable when prepared from $TiCl_3$ purified as a DME complex,²⁴³ and is capable of forming normal, medium, and large rings with comparable efficiency.

Ref. 244

The macrocyclization has proven useful in the formation of a number of natural products.²⁴⁵ These conditions have been used to prepare 36- and 72-membered rings.

Ref. 247

The double bonds were reduced to give the saturated compounds, so the double-bond configuration was not an immediate issue. It appears, however, that the *E*-double bonds are formed. The debenzylated derivatives of propan-1,2,3-triol occur as lipid components in various prokaryotes (archaeobacteria) that grow under extreme thermal conditions.

Under other conditions, reduction leads to diols. Reductive coupling to diols can be done using magnesium amalgam²⁴⁸ or zinc dust.²⁴⁹

The most general procedures are based on low-valent titanium. Good yields of diols are obtained from aromatic aldehydes and ketones by adding catechol to the TiCl_3 -Mg reagent prior to coupling.²⁵⁰

Both unsymmetrical alkenes and diols can be prepared by applying these methods to mixtures of two different carbonyl compounds. An excess of one component can be used to achieve a high conversion of the more valuable reactant. A mixed reductive

deoxygenation with TiCl_4 -Zn was used to prepare 4-hydroxytamoxifen, the active antiestrogenic metabolite of tamoxifen.

Ref. 251

Stereoselectivity has been observed in some coupling reactions of this type. For example, coupling with 4-hydroxy-3'-pivaloxybenzophenone was stereoselective for the *E*-isomer.

Ref. 252

It is not clear at this time what factors determine stereoselectivity.

Titanium-mediated reductive couplings are normally heterogeneous, and it was originally thought that the reactions take place at the metal surface.²⁵³ However, mechanistic study has suggested that Ti(II) may be the active species. Hydride reducing agents generate a solid having the composition $(\text{HTi}^{\text{II}}\text{Cl})_n$ that effects reductive couplings. This species is believed to react with carbonyl compounds with elimination of hydrogen to generate a complexed form of the carbonyl compound. The ketone in this complex is considered to be analogous to a “ketone dianion”²⁵⁴ and is strongly nucleophilic. This mechanism accounts for the characteristic “template effect” of the titanium reagents in promoting ring formation because it involves cooperating titanium ions.

It has been suggested that a similar mechanism operates under some conditions in which the reductant is generated in situ by a Zn-Cu couple.²⁵⁵ The key intermediate in this mechanism is a complex of the carbonyl compound with TiCl_2 . The formation

of alkene involves a second reduction step, which can occur at elevated temperature in the presence of excess reactant.

According to a DFT computational study, this mechanism is plausible.²⁵⁶

Samarium diiodide is another powerful one-electron reducing agent that can effect carbon-carbon bond formation under appropriate conditions.²⁵⁷ Aromatic aldehydes and aliphatic aldehydes and ketones undergo pinacol-type coupling with SmI_2 or SmBr_2 .

δ -Ketoaldehydes and 1,4-diketones are reduced to *cis*-cyclopentanediols.²⁵⁸ 1,5-Diketo compounds can be cyclized to cyclopentanediols, again with a preference for *cis*-diols.²⁵⁹ These reactions are believed to occur through successive one-electron transfer, radical cyclization, and a second electron transfer with Sm^{2+} either serving as a tether and Lewis acid, as well as being the reductant.

Many of the compounds used have additional functional groups, including ester, amide, ether, and acetal. These groups may be involved in coordination to samarium and thereby influence the stereoselectivity of the reaction.

The ketyl intermediates in SmI_2 reductions can be trapped by carbon-carbon double bonds, leading, for example, to cyclization of δ,ϵ -enones to cyclopentanols.

Ref. 261

SmI_2 has also been used to form cyclooctanols by cyclization of 7,8-enones.²⁶² These alkene addition reactions presumably proceed by addition of the ketyl radical to the double bond, followed by a second electron transfer.

The initial products of such additions under aprotic conditions are organosamarium reagents and further (tandem) transformations are possible, including addition to ketones, anhydrides, or carbon dioxide.

Ref. 263

Another reagent that has found use in pinacolic coupling is prepared from VCl_3 and zinc dust.²⁶⁴ This reagent is selective for aldehydes that can form chelated intermediates, such as β -formylamides, α -amidoaldehydes, α -phosphinoylaldehydes,²⁶⁵ and δ -ketoaldehydes.²⁶⁶ The vanadium reagent can be used for both homodimerization and heterodimerization. In the latter case, the reactive aldehyde is added to an excess of the second aldehyde. Under these conditions, the ketyl intermediate formed from the chelated aldehyde reacts with the second aldehyde.

The VCl_3 -Zn reagent has also been used in cyclization reactions, as in Entries 4 and 5 in Scheme 5.13.

There has been considerable discussion of the mechanism of the acyloin condensation. One formulation of the reaction envisages coupling of radicals generated by one-electron transfer.

An alternative mechanism bypasses the postulated α -diketone intermediate because its involvement is doubtful.²⁷⁰

Regardless of the details of the mechanism, the product prior to neutralization is the dianion of an α -hydroxy ketone, namely an enediolate. It has been found that the overall yields are greatly improved if trimethylsilyl chloride is present during the reduction to trap these dianions as trimethylsilyl ethers.²⁷¹ The silylated derivatives are much more stable to the reaction conditions than the enediolates. Hydrolysis during workup gives the acyloin product. This modified version of the reaction has been applied to cyclizations leading to small, medium, and large rings, as well as to intermolecular couplings.

Scheme 5.13 provides several examples of reductive carbon-carbon bond formation, including formation of diols, alkenes, and acyloins. Entry 1 uses magnesium amalgam in the presence of dichlorodimethylsilane. The role of the silane may be to

trap the pinacol as a cyclic siloxane. The reaction in Entry 2 is thought to involve Ti(II) as the active reductant and to proceed by a mechanism of the type described on p. 447. These conditions were also successful for the reaction shown in Entry 1. Entry 3 involves formation of a 14-membered ring using a low-valent titanium reagent. The product is a mixture of all four possible diastereomeric diols in yields ranging from 7 to 21%. Entry 4 is an example of a pinacol reduction using a vanadium reagent prepared in situ from VCl_3 and Zn, which tends to give a high proportion of *cis*-diol as a result of chelation with vanadium. Entry 5 shows the synthesis of a sensitive polyunsaturated lactam. The *cis*-diol was formed in 60% yield. In this particular case, various low-valent titanium reagents were unsuccessful. Entries 6 and 7 describe conditions that lead to alkene formation. Entries 8 to 10 are acyloin condensations. The reaction in Entry 8 illustrates the classical conditions. Entry 9 is an example of the reaction conducted in the presence of TMS-Cl to trap the enediolate intermediate and make the reaction applicable to formation of a four-membered ring. The example in Entry 10 uses sodium in the form of a solid deposit on an inert material. This is an alternative to the procedures that require dispersion of molten sodium in the reaction vessel (Entries 8 and 9).

5.7. Reductive Deoxygenation of Carbonyl Groups

Several methods are available for reductive removal of carbonyl groups from organic compounds. Reduction to methylene groups or conversion to alkenes can be achieved.

5.7.1. Reductive Deoxygenation of Carbonyl Groups to Methylene

Zinc and hydrochloric acid form a classical reagent combination for conversion of carbonyl groups to methylene groups, a reaction known as the *Clemmensen reduction*.²⁷² The corresponding alcohols are not reduced under the conditions of the

²⁷² E. Vedejs, *Org. React.*, **22**, 401 (1975).

reaction, so they are evidently not intermediates. The Clemmensen reaction works best for aryl ketones and is less reliable with unconjugated ketones. The mechanism is not known in detail but may involve formation of carbon-zinc bonds at the metal surface.²⁷³ The reaction is commonly carried out in hot concentrated hydrochloric acid with ethanol as a cosolvent. These conditions preclude the presence of acid-sensitive or hydrolyzable functional groups. A modification in which the reaction is run in ether saturated with dry hydrogen chloride gave good results in the reduction of steroidal ketones.²⁷⁴

The *Wolff-Kishner reaction*²⁷⁵ is the reduction of carbonyl groups to methylene groups by base-catalyzed decomposition of the hydrazone of the carbonyl compound. It is thought that alkylidimides are formed and then collapse with loss of nitrogen.²⁷⁶

The reduction of tosylhydrazones by $LiAlH_4$ or $NaBH_4$ also converts carbonyl groups to methylene.²⁷⁷ It is believed that a diimide is involved, as in the Wolff-Kishner reaction.

Excellent yields can also be obtained using $NaBH_3CN$ as the reducing agent.²⁷⁸ The $NaBH_3CN$ can be added to a mixture of the carbonyl compound and *p*-toluenesulfonylhydrazide. Hydrazone formation is faster than reduction of the carbonyl group by $NaBH_3CN$ and the tosylhydrazone is reduced as it is formed. Another reagent that can reduce tosylhydrazones to give methylene groups is $CuBH_4(PPh_3)_2$.²⁷⁹

Reduction of tosylhydrazones of α,β -unsaturated ketones by $NaBH_3CN$ gives alkenes with the double bond located between the former carbonyl carbon and the α -carbon.²⁸⁰ This reaction is believed to proceed by an initial conjugate reduction, followed by decomposition of the resulting vinylhydrazine to a vinylidene.

²⁸⁰. R. O. Hutchins, M. Kacher, and L. Rua, *J. Org. Chem.*, **40**, 923 (1975).

Catecholborane or sodium borohydride in acetic acid can also be used as a reducing reagent in this reaction.²⁸¹

Carbonyl groups can be converted to methylene groups by desulfurization of thioketals. The cyclic thioketal from ethanedithiol is commonly used. Reaction with excess Raney nickel causes hydrogenolysis of both C–S bonds.

Ref. 282

Other reactive forms of nickel including nickel boride²⁸³ and nickel alkoxide complexes²⁸⁴ can also be used for desulfurization. Tri-*n*-butyltin hydride is an alternative reagent for desulfurization.²⁸⁵

Scheme 5.14 illustrates some representative carbonyl deoxygenations. Entries 1 and 2 are Clemmensen reductions of acyl phenols. Entry 3 is an example of the Wolff-Kishner reaction. Entry 4 describes modified conditions for the Wolff-Kishner reaction that take advantage of the strong basicity of the KO^tBu-DMSO combination. Entries 5 to 7 are examples of conversion of sulfonylhydrazones to methylene groups (Caglioti reaction). In addition to LiAlH₄, which was used in the original procedure, NaBH₃CN (Entry 6) and catecholborane (Entry 7) can be used as reducing agents. Entries 8 and 9 are thioketal desulfurizations.

5.7.2. Reduction of Carbonyl Compounds to Alkenes

Ketone *p*-toluenesulfonylhydrazones are converted to alkenes on treatment with strong bases such as an alkyllithium or lithium dialkylamide.²⁸⁶ Known as the *Shapiro reaction*,²⁸⁷ this proceeds through the anion of a vinylidene, which decomposes to a vinyl lithium reagent. Treatment of this intermediate with a proton source gives the alkene.

The Shapiro reaction has been particularly useful for cyclic ketones, but its scope includes acyclic systems as well. In the case of unsymmetrical acyclic ketones,

questions of both regiochemistry and stereochemistry arise. 1-Octene is the exclusive product from 2-octanone.²⁸⁸

This regioselectivity has been shown to depend on the stereochemistry of the C=N bond in the starting hydrazone. There is evidently a strong preference for abstracting the proton *syn* to the arenesulfonyl group, probably because this permits chelation with the lithium ion.

The Shapiro reaction converts the *p*-toluenesulfonylhydrazones of α,β -unsaturated ketones to dienes (see Entries 3 to 5 in Scheme 5.14).²⁸⁹

The vinyl lithium reagents generated in the Shapiro reaction can be used in tandem reactions. In the reaction shown below, a hydroxymethyl group was added by formylation followed by reduction.

In another example, a sequence of methylation-elimination-hydroxymethylation was used to install the functionality pattern found in the A-ring of taxol. The hydrazone dianion was generated and methylated at low temperature. The hydrazone was then deprotonated again using excess *n*-butyllithium and allowed to warm to room temperature, at which point formation of the vinyl lithium occurred. Reaction with paraformaldehyde generated the desired product.²⁹⁰

Scheme 5.15 shows some examples of the Shapiro reaction. Entry 1 is an example of the standard procedure, as documented in *Organic Syntheses*. Entry 2 illustrates the preference for the formation of the less-substituted double bond. Entries 3, 4, and 5 involve tosylhydrazone of α,β -unsaturated ketones. The reactions proceed by α' -deprotonation. Entry 6 illustrates the applicability of the reaction to a highly strained system.

5.8. Reductive Elimination and Fragmentation

The presence of a potential leaving group β to the site of carbanionic character usually leads to β -elimination. In some useful synthetic procedures, the carbanionic character is generated by a reductive process.

Similarly, carbanionic character δ to a leaving group can lead to β , γ -fragmentation.

A classical example of the β -elimination reaction is the reductive debromination of vicinal dibromides. Zinc metal is the traditional reducing agent.²⁹¹ A multitude of other reducing agents have been found to give this and similar reductive eliminations. Some examples are given in Table 5.7. Some of the reagents exhibit *anti* stereospecificity, whereas others do not. A stringent test for *anti* stereospecificity is the extent of *Z*-alkene formed from a *syn* precursor.

Anti stereospecificity is associated with a concerted reductive elimination, whereas single-electron transfer fragmentation leads to loss of stereospecificity and formation of the more stable *E*-stereoisomer.

As vicinal dibromides are usually made by bromination of alkenes, their utility for synthesis is limited, except for temporary masking of a double bond. Much more frequently it is desirable to convert a diol to an alkene, and several useful procedures have been developed. The reductive deoxygenation of diols via thiono carbonates was

developed by Corey and co-workers.²⁹² Triethyl phosphite is useful for many cases, but the more reactive 1,3-dimethyl-2-phenyl-1,3,2-diazaphospholidine can be used when milder conditions are required.²⁹³ The reaction presumably occurs by initial P–S bonding followed by a concerted elimination of carbon dioxide and the thiophosphoryl compound.

Diols can also be deoxygenated via *bis*-sulfonate esters using sodium naphthalenide.²⁹⁴ Cyclic sulfate esters are also cleanly reduced by lithium naphthalenide.²⁹⁵

This reaction, using sodium naphthalenide, has been used to prepare unsaturated nucleosides.

Ref. 296

It is not entirely clear whether these reactions involve a redox reaction at sulfur or if they proceed by organometallic intermediates.

Iodination reagents combined with aryl phosphines and imidazole can also effect reductive conversion of diols to alkenes. One such combination is 2,4,5-triiodoimidazole, imidazole, and triphenylphosphine.²⁹⁷ These reagent combinations

are believed to give oxyphosphonium intermediates, which then can serve as leaving groups, forming triphenylphosphine oxide as in the Mitsunobu reaction (see Section 3.2.3). The iodide serves as both a nucleophile and reductant.

In a related procedure, chlorodiphenylphosphine, imidazole, iodine, and zinc cause reductive elimination of diols.²⁹⁸ β -Iodophosphinate esters can be shown to be intermediates in some cases.

Another alternative for conversion of diols to alkenes is the use of the Barton radical fragmentation conditions (see Section 5.5) with a silane hydrogen atom donor.²⁹⁹

N-Ethylpiperidinium hypophosphite has been used as a reductant in deoxygenation of nucleoside diol xanthates in aqueous solution.³⁰⁰

The reductive elimination of β -hydroxysulfones is the final step in the *Julia-Lythgoe alkene synthesis* (see Section 2.4.3).³⁰¹ The β -hydroxysulfones are normally obtained by an aldol addition.

Concerted Cycloadditions, Unimolecular Rearrangements, and Thermal Eliminations

Introduction

Most of the reactions described in the preceding chapters involve polar or polarizable reactants and proceed through polar intermediates and/or transition structures. One reactant can be identified as nucleophilic and the other as electrophilic. Carbanion alkylations, nucleophilic additions to carbonyl groups, and electrophilic additions to alkenes are examples of such reactions. The reactions to be examined in this chapter, on the other hand, occur via a reorganization of electrons through transition structures that may not be much more polar than the reactants. These reactions proceed through cyclic transition structures. The activation energy can be provided by thermal or photochemical excitation of the reactant(s) and often no other reagents are involved. Most of the transformations fall into the category of *concerted pericyclic reactions*, in which there are no intermediates and the transition structures are stabilized by favorable orbital interactions, as discussed in Chapter 10 of Part A. These reactions can be classified into three broad types: cycloadditions, unimolecular rearrangements, and eliminations. We also discuss some reactions that effect closely related transformations, but which on mechanistic scrutiny are found to proceed through discrete intermediates.

6.1. Diels-Alder Reactions

6.1.1. The Diels-Alder Reaction: General Features

Cycloaddition reactions result in the formation of a new ring from two reactants. A concerted mechanism requires that a single transition state, and therefore no intermediate, lie on the reaction path between reactants and adduct. The most important example of cycloaddition is the *Diels-Alder (D-A) reaction*. The cycloaddition of alkenes and dienes is a very useful method for forming substituted cyclohexenes.¹

A clear understanding of concerted cycloaddition reactions developed as a result of the formulation of the mechanisms within the framework of molecular orbital theory. Consideration of the MOs of reactants and products reveals that in many cases a smooth transformation of the orbitals of the reactants to those of products is possible. In other cases, reactions that might appear feasible if no consideration is given to the symmetry and spatial orientation of the orbitals are found to require high-energy TSs when the orbitals are considered in detail. (Review Section 10.1 of Part A for a discussion of the orbital symmetry analysis of cycloaddition reactions.) The relationships between reactants and TS orbitals permit description of potential cycloaddition reactions as “allowed” or “forbidden” and indicate whether specific reactions are likely to be energetically favorable. The same orbital symmetry relationships that are informative as to the feasibility of a reaction are often predictive of the regiochemistry and stereochemistry. This predictability is an important feature for synthetic purposes. Another attractive aspect of the D-A reaction is the fact that *two new carbon-carbon bonds* are formed in a single reaction.

In the terminology of orbital symmetry classification, the Diels-Alder reaction is a $[4\pi_s + 2\pi_s]$ cycloaddition, an allowed process. There have been a large number of computational studies of the D-A reaction, and as it is a fundamental example of a concerted reaction, it has frequently been the subject of advanced calculations.² These studies support a concerted mechanism, which is also supported by good agreement between experimental and calculated (B3LYP/6-31G*) kinetic isotope effects.³ The TS for a concerted reaction requires that the diene adopt the *s-cis* conformation. The diene and substituted alkene (called the *dienophile*) approach each other in approximately parallel planes. The symmetry properties of the π orbitals permit stabilizing interactions between C(1) and C(4) of the diene and the dienophile. Usually, the strongest bonding

Fig. 6.1. Interaction between LUMO of dienophile and HOMO of diene in the Diels-Alder reaction.

interaction is between the HOMO of the diene and the LUMO of the dienophile. The interaction between the frontier orbitals is depicted in Figure 6.1.

6.1.2. Substituent Effects on the Diels-Alder Reaction

There is a strong electronic substituent effect on the D-A reaction. The most reactive dienophiles for simple dienes are those having electron-attracting groups. Thus, quinones, maleic anhydride, and nitroalkenes are among the most reactive dienophiles. α,β -Unsaturated aldehydes, esters, ketones, and nitriles are also effective dienophiles. It is significant that if an electron-poor diene is utilized, the preference is reversed and electron-rich alkenes, such as vinyl ethers, are the best dienophiles. Such reactions are called *inverse electron demand Diels-Alder reactions*, and the relationships involved are readily understood in terms of frontier orbital theory. Electron-rich dienes have high-energy HOMOs and interact strongly with the LUMOs of electron-poor dienophiles. When the substituent pattern is reversed and the diene is electron-poor, the strongest interaction is between the dienophile HOMO and the diene LUMO.

Frontier orbital theory can also explain the regioselectivity observed when both the diene and alkene are unsymmetrically substituted.⁴ Generally, there is a preference

⁴. K. N. Houk, *Acc. Chem. Res.*, **8**, 361 (1975); I. Fleming, *Frontier Orbitals and Organic Chemical Reactions*, Wiley-Interscience, New York, 1976; O. Eisenstein, J. M. LeFour, N. T. Anh, and R. F. Hudson, *Tetrahedron*, **33**, 523 (1977).

for the “*ortho*” product when the diene has a donor (ERG) substituent at C(1) and for “*para*” product when the diene has an ERG at C(2), as in the examples shown.⁵

When the dienophile bears an EWG substituent and the diene an ERG, the strongest interaction is between the HOMO of the diene and the LUMO of the dienophile. The reactants are oriented so that the carbons having the highest coefficients of these two frontier orbitals can begin the bonding process, and this leads to the observed regiochemical preference as summarized in Figure 6.2.

Diels-Alder reactions are *stereospecific* with respect to the *E*- and *Z*-relationships in both the dienophile and the diene. For example, addition of dimethyl fumarate and dimethyl maleate with cyclopentadiene is completely stereospecific with respect to the *cis* or *trans* orientation of the ester substituents.

Ref. 6

Ref. 7

Similarly, *E,E*-2,4-hexadiene gives a product that is stereospecific with respect to the diene methyl groups.

a) Coefficient at C(2) is higher than at C(1) in the LUMO of a dienophile bearing an electron-withdrawing substituent.

(b) Coefficient at C(4) is higher than at C(1) in HOMO of a diene bearing an electron-releasing substituent at C(1).

(c) Coefficient at C(1) is higher than at C(4) in HOMO of a diene bearing an electron-releasing substituent at C(1).

(d) The regioselectivity of the Diels-Alder reaction corresponds to matching the carbon atoms having the largest coefficients of the frontier orbitals.

Fig. 6.2. HOMO-LUMO interactions rationalize regioselectivity of Diels-Alder reactions.

Stereospecificity also is exhibited for dienes having stronger electron-releasing groups, such as trimethylsiloxy.

Ref. 9

⁹ M. E. Jung and C. A. McCombs, *Org. Synth.*, **58**, 163 (1978); M. E. Jung and C. A. McCombs, *Tetrahedron Lett.*, 2935 (1976).

For an unsymmetrical dienophile there are two possible stereochemical orientations with respect to the diene, *endo* and *exo*, as illustrated in Figure 6.3. In the *endo* TS the reference substituent on the dienophile is oriented toward the π orbitals of the diene. In the *exo* TS the substituent is oriented away from the π system. For many substituted butadiene derivatives, the TSs lead to two different stereoisomeric products. The *endo* mode of addition is usually preferred when an electron-attracting substituent such as a carbonyl group is present on the dienophile. The empirical statement that describes this preference is called the *Alder rule*. Frequently a mixture of both stereoisomers is formed and sometimes the *exo* product predominates, but the Alder rule is a useful initial guide to prediction of the stereochemistry of a D-A reaction. The *endo* product is often the more sterically congested. The preference for the *endo* TS is strongest for relatively rigid dienophiles such as maleic anhydride and benzoquinone. For methyl acrylate, methyl methacrylate, and methyl crotonate the selectivity ratios are not high.¹⁰ The preference for the *endo* TS increases somewhat with increasing solvent polarity.¹¹ This has been attributed to a higher polarity of the *endo* TS, resulting from alignment of the dipoles.

The preference for the *endo* TS is considered to be the result of interaction between the dienophile substituent and the π electrons of the diene. These are called *secondary orbital interactions*. Dipolar attractions and van der Waals attractions may also be involved.¹² Some *exo-endo* ratios for thermal D-A reactions of cyclopentadiene are

Fig. 6.3. *Endo* (a) and *exo* (b) stereochemistry in Diels-Alder reactions.

given in Table 6.1. Most of the data pertain to dienophiles with carbonyl substituents. Note that tetrahedral noncarbonyl EWGs such as sulfonyl and phosphonyl also exhibit a small preference for the *endo* TS. The cyano group shows little *endo:exo* preference. Both α - and β -methyl groups result in more *exo* product, as seen for the methyl-substituted esters and nitriles. As we will see shortly, the use of Lewis acid catalysts usually increases the preference for the *endo* TS.

Steric effects play a dominant role with more highly substituted dienes. Hexachlorocyclopentadiene, for example, shows a higher *endo* preference than cyclopentadiene because the 5-chlorine causes steric interference with *exo* substituents.¹³

Cyclic α -methylene ketones and lactones, in which the *syn* conformation is enforced, give predominantly *exo* adducts.¹⁴

¹³. K. L. Williamson, Y.-F. L. Hsu, R. Lacko, and C. H. Youn, *J. Am. Chem. Soc.*, **91**, 6129 (1969).

¹⁴. F. Fotiadu, F. Michel, and G. Buono, *Tetrahedron Lett.*, **31**, 4863 (1990); J. Mattay, J. Mertes, and G. Maas, *Chem. Ber.*, **122**, 327 (1989).

It has been suggested that this is due to a more favorable alignment of dipoles in the *exo* TS.¹⁵

Computational studies predict a preference for the *endo* TS.¹⁶ There have been several computational efforts to dissect the various factors that contribute to the differences between the *exo* and *endo* TS.¹⁷ These generally are in agreement with the experimental preference for the *endo* TS, but there is no consensus on the dominant factors in this preference.¹⁸

Diels-Alder cycloadditions are sensitive to steric effects of two major types in the diene. Bulky substituents on the termini of the diene hinder approach of the two components to each other and decrease the rate of reaction. This effect can be seen in the relative reactivity of 1-substituted butadienes toward maleic anhydride.¹⁹

R	k_{rel} (25°C)
-H	1
-CH ₃	4.2
-C(CH ₃) ₃	<0.05

Substitution of hydrogen by methyl results in a slight rate *increase* as a result of the electron-releasing effect of the methyl group. A *t*-butyl substituent produces a large rate *decrease* because the steric effect is dominant.

Another type of steric effect results from interactions between diene substituents. Adoption of the *s-cis* conformation of the diene in the TS brings the *cis*-oriented 1- and 4-substituents on a diene close together. *E*-1,3-Pentadiene is 10³ times more reactive than 4-methyl-1,3-pentadiene toward the very reactive dienophile tetracyanoethylene. This is because the unfavorable interaction between the additional methyl substituent and the C(1) hydrogen in the *s-cis* conformation raises the energy of the TS.²⁰

R	k_{rel}
-H	1
-CH ₃	10 ⁻³

Relatively small substituents at C(2) and C(3) of the diene exert little steric influence on the rate of D-A addition. 2,3-Dimethylbutadiene reacts with maleic anhydride about ten times faster than butadiene owing to the electronic effect of the methyl

groups. 2-*t*-Butyl-1,3-butadiene is 27 times more reactive than butadiene. The *t*-butyl substituent favors the *s-cis* conformation because of steric repulsions in the *s-trans* conformation.

The presence of a *t*-butyl substituent on *both* C(2) and C(3), however, prevents attainment of the *s-cis* conformation, and D-A reactions of 2,3-di-(*t*-butyl)-1,3-butadiene have not been observed.²¹

6.1.3. Lewis Acid Catalysis of the Diels-Alder Reaction

Lewis acids such as zinc chloride, boron trifluoride, tin tetrachloride, aluminum chloride, methylaluminum dichloride, and diethylaluminum chloride catalyze Diels-Alder reactions.²² The catalytic effect is the result of coordination of the Lewis acid with the dienophile. The complexed dienophile is more electrophilic and more reactive toward electron-rich dienes. The mechanism of the addition is believed to be concerted and enhanced regio- and stereoselectivity is often observed.²³

	Product ratio

The stereoselectivity of any particular reaction depends on the details of the structure of the TS. The structures of several enone-Lewis acid complexes have been determined by X-ray crystallography.²⁵ The site of complexation is the carbonyl oxygen, which maintains a trigonal geometry, but with somewhat expanded angles (130° – 140°). The Lewis acid is normally *anti* to the larger carbonyl substituent. Boron trifluoride complexes are tetrahedral, but Sn(IV) and Ti(IV) complexes can be tetrahedral, bipyramidal or octahedral. The structure of the 2-methylpropenal- BF_3 complex in Figure 6.4 is illustrative.²⁶ Chelation can favor a particular structure. For example, *O*-acryloyl lactates adopt a chelated hexacoordinate structure with TiCl_4 , as shown in Figure 6.5.²⁷

Computational studies have explored the differences between thermal and Lewis acid-catalyzed D-A reactions. Ab initio calculations ($\text{HF}/6\text{-}31\text{G}^*$) have been used to compare the energy of four possible TSs for the D-A reaction of the BF_3 complex of propenal with 1,3-butadiene.^{16d} The TSs are designated *endo* and *exo* and *s-cis* and *s-trans*. The latter designations refer to the dienophile conformation. The results are summarized in Figure 6.6. In the thermal reaction, the *endo-cis* and *exo-cis* TSs are nearly equal in total and activation energies. In the BF_3 -catalyzed reaction, the

<i>Endo-cis</i>	0.00	32.7	<i>Endo-cis</i>	0.00	23.2
<i>Endo-trans</i>	1.24	33.9	<i>Endo-trans</i>	2.25	25.7
<i>Exo-cis</i>	0.06	32.7	<i>Exo-cis</i>	1.72	24.3
<i>Exo-trans</i>	1.93	34.5	<i>Exo-trans</i>	5.61	28.3

Fig. 6.6. Relative energies of four possible transition structures for Diels-Alder reaction of 1,3-butadiene and propenal, with and without BF_3 catalyst. Geometric parameters of the most stable transition structures (*endo-cis*) are shown. Adapted from *J. Am. Chem. Soc.*, **120**, 2415 (1998), by permission of the American Chemical Society.

endo-cis TS is favored by 1.7 kcal/mol. The calculated ΔG^* is reduced by nearly 10 kcal/mol for the catalyzed reaction, relative to the thermal reaction. The catalyzed reaction shows significantly greater asynchronicity than the thermal reaction. In the BF_3 -catalyzed reaction, the forming bond distances are 2.06 and 2.96 Å, whereas in the thermal reaction they are 2.04 and 2.65 Å. (See Topic 10.1 of Part A for discussion of asynchronicity.)

A similar study was done with methyl acrylate as the dienophile.²⁸ The uncatalyzed and catalyzed TSs are shown in Figure 6.7. As with propenal, the catalyzed reaction is quite asynchronous with C(2)–C(3) bonding running ahead of C(1)–C(6) bonding. In this system, there is a shift from favoring the *exo-s-cis* TS in the thermal reaction to the *endo-s-trans* TS in the catalyzed reaction. A large component in this difference is the relative stability of the free and complexed dienophile. The free dienophile favors the *s-cis* conformation, whereas the BF_3 complex favors the *s-trans* conformation.

Visual models, additional information and exercises on the Diels-Alder Reaction can be found in the Digital Resource available at: Springer.com/carey-sundberg.

In terms of both the effect of substituents and Lewis acid catalysis, the rates of D-A reactions *increase as the donor-acceptor character of the reactive*

complex increases. That is, the better the donor substituents in the diene and the stronger the acceptor substituents in the dienophile, the faster the reaction. Similarly, the more electrophilic the Lewis acid, the faster the reaction. In extreme cases, cycloaddition may become stepwise.

Such a stepwise reaction would not be expected to change the regiochemistry of cycloaddition, but it could lead to loss of stereospecificity if the zwitterionic intermediate has a long enough lifetime. In most reactions where only carbon-carbon bonds are being formed, the D-A reaction remains stereospecific.

In one study, the mechanisms of the reaction of methyl cinnamate and cyclopentadiene with BF_3 , AlCl_3 , and catecholborane bromide as catalysts were compared.²⁹ According to these computations (B3LYP/6-31G*), the uncatalyzed and BF_3 - and AlCl_3 -catalyzed reactions proceed by asynchronous concerted mechanisms, but a

²⁹ C. N. Alves, F. F. Camilo, J. Gruber, and A. B. F. da Silva, *Chem. Phys.*, **306**, 35 (2004).

stepwise mechanism is found with catecholborane bromide. Experimentally, this is the only catalyst that is effective for this reaction.³⁰

Metal cations can catalyze reactions of certain dienophiles. For example, Cu^{2+} strongly catalyzes addition reactions of 2-pyridyl styryl ketones, presumably through a chelate involving the carbonyl oxygen and pyridine nitrogen.³¹

This reaction has been studied computationally with Zn^{2+} as the metal cation.³² The calculations indicate that a stepwise reaction occurs, beginning with electrophilic attack of the complexed dienophile on the diene.

Some D-A reactions are catalyzed by high concentrations of LiClO_4 in ether,³³ a catalysis that involves Lewis acid complexation of Li^+ with the dienophile.³⁴

The LiClO_4 -diethyl ether system shows a considerable dependency on concentration, with the maximal effect around 5 M, which may be due to the detailed structure of LiClO_4 in ether. The optimum reactivity may be associated with a monosolvate. Dilute solutions have more of the dietherate, whereas in more concentrated solution LiClO_4 may form less reactive aggregates.³⁵ $\text{LiN}(\text{SO}_2\text{SCF}_3)_2$ has been recommended as an alternative to avoid the use of a perchlorate salt.³⁶

Lithium *tetrakis*-(3,5-difluoromethyl)borate, which provides an unsolvated lithium cation in noncoordinating solvents, exhibits a several thousandfold catalysis of the reaction of cyclopentadiene and methyl vinyl ketone.³⁷ Lithium tetrafluoroborate is also an effective catalyst and in some instances has worked when LiClO_4 has failed, such as in the intramolecular reaction shown below.³⁸

Scandium triflate has been found to catalyze D-A reactions.³⁹ For example, with 10 mol % $\text{Sc}(\text{O}_3\text{SCF}_3)_3$ present, isoprene and methyl vinyl ketone react to give the expected adduct in 91% yield after 13 h at 0°C.

Among the unique features of $\text{Sc}(\text{O}_3\text{SCF}_3)_3$ is its ability to function as a catalyst in hydroxylic solvents. Other dienophiles, including *N*-acryloyloxazolidinones, also are subject to catalysis by $\text{Sc}(\text{O}_3\text{SCF}_3)_3$. Indium trichloride is another Lewis acid that can act as a catalyst in aqueous solution.⁴⁰

Reversible O-silylation also enhances the electrophilicity of carbonyl dienophiles. For example, 10 mol % *N*-trimethylsilyl triflimide catalyzes the reaction of pent-3-en-2-one with cyclopentadiene. A hindered base, such as 2,6-*bis*-*t*-butyl-4-methylpyridine improves the yield in cases in which the catalyst causes the occurrence of reactant degradation.

Ref. 41

The solvent also has an important effect on the rate of D-A reactions. The traditional solvents were nonpolar organic solvents such as aromatic hydrocarbons. However, water and other highly polar solvents, such as ethylene glycol and formamide, accelerate a number of D-A reactions.⁴² The accelerating effect of water is attributed to “enforced hydrophobic interactions.” That is, the strong hydrogen-bonding network in water tends to exclude nonpolar solutes and force them together, resulting in higher effective concentrations and relative stabilization of the developing TS.⁴³ More specific hydrogen bonding with the TS also contributes to the rate acceleration.⁴⁴

Fig. 6.8. Proposed hydrogen bonding in TS for addition of **1** and **2**. Reproduced from *Tetrahedron Lett.*, **45**, 4777 (2004), by permission of Elsevier.

Hydrogen-bonding interactions can be designed into reaction systems. For example, the reactants **1** and **2** were found to react much more rapidly than the corresponding ester and to give exclusively the *exo* product.⁴⁵ Molecular mechanics and spectroscopic studies indicate that the hydrogen-bonding pattern shown in Figure 6.8 is responsible.

To summarize the key points, D-A reactions are usually concerted processes. The regio- and stereoselectivity can be predicted by applying FMO analysis. The reaction between electron donor dienes and electron acceptor dienophiles is facilitated by Lewis acids, polar solvents, and favorable hydrogen-bonding interactions. The D-A reaction is quite sensitive to steric factors, which can retard the reaction and also influence the stereoselectivity with respect to *exo* or *endo* approach.

6.1.4. The Scope and Synthetic Applications of the Diels-Alder Reaction

Schemes 10.1 and 10.4 of Part A, respectively, give the structure of a number of typical dienophiles and show representative D-A reactions involving relatively simple reactants. The D-A reaction is frequently used in synthesis and can either be utilized early in a process to construct basic ring structures or to bring together two subunits in a convergent synthesis. The intramolecular version, which will be discussed in section 6.1.7, can be used to construct two new rings.

The virtues of the D-A reaction include its ability to create a cyclohexene ring by formation of *two new bonds with predictable regiochemistry*. The reaction can also create as many as four contiguous stereogenic centers. The stereoselectivity is also often predictable on the basis of the *supra-supra* stereospecificity and considerations of the preference for the *endo* or *exo* TS.

6.1.4.1. Examples of Dienes and Dienophiles. The synthetic value of D-A reactions can be enhanced in various ways. In addition to hydrocarbon dienes, substituted dienes can be used to introduce functional groups into the products. One example that illustrates the versatility of such reagents is 1-methoxy-3-trimethylsiloxy-1,3-butadiene

⁴⁵ R. J. Pearson, E. Kassianidis, and D. Philip, *Tetrahedron Lett.*, **45**, 4777 (2004).

(*Danishefsky's diene*).⁴⁶ The two donor substituents provide strong regiochemical control. The D-A adducts are trimethylsilyl enol ethers that can be readily hydrolyzed to ketones. The β -methoxy group is often eliminated during hydrolysis, resulting in formation of cyclohexenones.

A milder protocol for the conversion to enones involves use of a catalytic amount of TMSOTf and a pyridine base.⁴⁷

The desilylation is also promoted by various Lewis acids, Yb(OTf)₃ being among the most effective. This catalyst can be used in a one-pot sequence in which it promotes both the cycloaddition and subsequent elimination.⁴⁸

An analogous silyoxydienamine shows a similar reactivity pattern.⁴⁹

2-(Diethoxyphosphoryloxy)-1,3-butadiene and 2-(diethoxyphosphoryloxy)-1,3-pentadiene are good dienes and are compatible with Lewis acid catalysts.⁵⁰ They exhibit the regioselectivity expected for a donor substituent and show a preference for *endo* addition with enones.

Unstable dienes can be generated in situ in the presence of a dienophile. Among the most useful examples are the *ortho*-quinodimethanes. These compounds are exceedingly reactive as dienes because the cycloaddition reestablishes a benzenoid ring and results in aromatic stabilization.⁵¹

There are several general routes to quinodimethanes. One is pyrolysis of benzocyclobutenes.⁵²

This reaction can be applied to substituted benzocyclobutenes. For example, the reaction has been used to form an array of five linear rings containing most of the functionality for the antibiotic tetracycline.

Ref. 53

1,4-Eliminations from α, α' -*ortho*-disubstituted benzenes can be carried out with various potential leaving groups. Benzylic silyl substituents can serve as the carbanion precursors.

Several procedures have been developed for obtaining quinodimethane intermediates from *o*-substituted benzylstannanes. The reactions occur by generating an electrophilic center at the adjacent benzylic position, which triggers a 1,4-elimination.

Specific examples include treatment of *o*-stannyl benzyl alcohols with TFA,⁵⁵ reactions of ketones and aldehydes with Lewis acids,⁵⁶ and electrophilic selenation of styrenes.⁵⁷

o-Dibromomethylbenzenes can be converted to quinodimethanes with reductants such as zinc, nickel, chromous ion, and tri-*n*-butylstannide.⁵⁸

Quinodimethanes have been especially useful in intramolecular D-A reactions, as is illustrated in Section 6.1.7.

Pyrones are useful dienes, although they are not particularly reactive. The adducts have the potential for elimination of carbon dioxide, resulting in the formation of an aromatic ring. Pyrones react best with electron-rich dienophiles. Vinyl ethers are frequently used as dienophiles with pyrones. The regiochemical preference places the dienophile donor *ortho* to the pyrone carbonyl.

Ref. 60

These reactions can be catalyzed by Lewis acids such as *bis*-alkoxytitanium dichlorides⁶¹ and lanthanide salts.⁶²

Another type of special diene, the polyaza benzene heterocyclics, such as triazines and tetrazines, is discussed in Section 6.6.2.

The synthetic utility of the D-A reaction can be expanded by the use of dienophiles that contain *masked functionality* and are the *synthetic equivalents* of unreactive or inaccessible compounds. (See Section 13.1.2 for a more complete discussion of the concept of synthetic equivalents.) For example, α -chloroacrylonitrile shows satisfactory reactivity as a dienophile. The α -chloronitrile functionality in the adduct can be hydrolyzed to a carbonyl group. Thus, α -chloroacrylonitrile can function as the equivalent of ketene, $\text{CH}_2=\text{C}=\text{O}$,⁶³ which is not a suitable dienophile because it has a tendency to react with dienes by $[2+2]$ cycloaddition, rather than the desired $[4+2]$ fashion.

Nitroalkenes are good dienophiles and the variety of transformations available for nitro groups makes them versatile intermediates.⁶⁵ Nitro groups can be converted to carbonyl groups by reductive hydrolysis, so nitroethylene can be used as a ketene equivalent.⁶⁶

Ref. 67

Vinyl sulfones are reactive as dienophiles. The sulfonyl group can be removed reductively with sodium amalgam (see Section 5.6.2). In this two-step reaction sequence, the vinyl sulfone functions as an ethylene equivalent. The sulfonyl group also permits alkylation of the adduct, via the carbanion. This three-step sequence permits the vinyl sulfone to serve as the synthetic equivalent of a terminal alkene.⁶⁸

Phenyl vinyl sulfoxide can serve as an acetylene equivalent. Its D-A adducts can undergo thermal elimination of benzenesulfenic acid.

Cis- and *trans*-*bis*-benzenesulfonylethene are also acetylene equivalents. The two sulfonyl groups undergo reductive elimination on reaction with sodium amalgam.

Ref. 70

Vinylphosphonium salts are reactive as dienophiles as a result of the EWG character of the phosphonium substituent. The D-A adducts can be deprotonated to give ylides that undergo the Wittig reaction to introduce an exocyclic double bond. This sequence of reactions corresponds to a D-A reaction employing allene as the dienophile.⁷¹

The use of 2-vinyldioxolane, the ethylene glycol acetal of acrolein, as a dienophile illustrates application of the masked functionality concept in a different way. The acetal itself would not be expected to be a reactive dienophile, but in the presence of a catalytic amount of acid the acetal is in equilibrium with the electrophilic oxonium ion.

Diels-Alder addition occurs through this cationic intermediate at room temperature.⁷² Similar reactions occur with substituted alkenyldioxolanes.

This reaction has been used to construct the carbon skeleton found in dysidiolide, a cell cycle inhibitor isolated from a marine sponge.⁷³ In this case, the reactive oxonium ion intermediate was generated by O-silylation.

6.1.4.2. Synthetic Applications of the Diels-Alder Reaction. Diels-Alder reactions have long played an important role in synthetic organic chemistry.⁷⁴ The reaction of a substituted benzoquinone and 1,3-butadiene, for example, was the first step in one of the early syntheses of steroids. The angular methyl group was introduced by the methyl group on the quinone and the other functional groups were used for further elaboration.

Ref. 75

In a synthesis of gibberellic acid, a diene and quinone, both with oxygen-substituted side chains, gave the initial intermediate. Later in the synthesis, an intramolecular D-A reaction was used to construct the A-ring.

Ref. 76

Functionality can be built into either the diene or dienophile for purposes of subsequent transformations. For example, in the synthesis of prephenic acid, the diene has the capacity to generate an enone. The dienophile contains a sulfoxide substituent that is subsequently used to introduce a second double bond by elimination.

Scheme 6.1 gives some additional examples of application of thermal D-A reactions in syntheses. The reaction in Entry 1 was eventually used to construct an aromatic ring by decarboxylation and aromatization. The reaction did not exhibit much facial selectivity, but this was irrelevant for the particular application. Entry

2 illustrates the use of high pressure to accelerate reaction. This reaction gives only an *endo* product, since both the electronic effect of the formyl group and the steric effect of the sulfonamido group favor this orientation. The reaction in Entry 3 involves a typical diene and dienophiles. The reaction is completely regioselective in the direction expected [donor alkyl groups at C(1) and C(3) of the diene unit] and is also completely *endo* selective. The facial selectivity with respect to the diene, however, is only 3.3:1. Entry 4 is an example of the use of nitroethene as an ethene equivalent. The nitro group was removed by reduction with Bu_3SnH . The reaction in Entry 5 involves a diene unit activated by a 2-siloxy substituent. On exposure to acid, this provides the product as a ketone. The reaction is evidently completely regio- and stereoselective. Entry 6 involves a doubly activated diene. The aromatic ring is formed by extrusion of isobutylene from a bicyclic intermediate. Entry 7 involves the ring opening of a benzocyclobutene to a quinodimethane. In this case, aromatization occurs as the result of the loss of two methoxy groups.

Owing to their advantages in terms of the lower temperature required and the higher regio- and stereoselectivity, Lewis acid-catalyzed D-A reactions are often preferable to the corresponding thermal version. Scheme 6.2 gives some examples of D-A reactions catalyzed by Lewis acids. Entries 1 and 2 are cases with substituent groups on the reacting bonds. Systems of this type are often relatively unreactive in thermal D-A reactions. The reaction in Entry 2 is an inverse electron demand case, and the catalyst activates the *diene* rather than the dienophile. Entry 3 involves a relatively highly substituted diene. The reaction was used to create a structure corresponding to the A-ring of the antitumor substance taxol. Entries 4, 5, and 6 involve dienes that have donor substituents that impart regioselectivity. The products of each of the reactions result from *endo* addition. The reaction in Entry 4 involves a cyclohexenone dienophile. 5-Substituted cyclohexenones have a strong preference for *anti* approach relative to the substituent.⁷⁸ The isopropenyl substituent establishes a conformational preference and the diene approaches from the *anti* direction.

Entries 5 and 6 exhibit the “ortho” regioselectivity expected for a 1-ERG on the diene. These dienes also present the possibility for competing Lewis acid coordination sites in the diene that would be expected to be *deactivating*. In Entry 6, the phenyl substituent on the oxazolidinone ring establishes a facial preference. The dienophiles in Entries 7 and 8 have both ERG and EWG substituents (sometimes called capto-dative dienophiles). The regiochemistry is consistent with the acceptor substituent having the dominant influence.⁷⁹ Entry 9 illustrates the excellent regio- and stereoselectivity often seen for Lewis acid-catalyzed reactions. Only a single product was found.

Entries 10 and 11 involve lactones and lactams, respectively. The catalyst used in Entry 10 is thought to be capable of interaction with both the carbonyl and ether oxygens.

In Entry 11 the dienophile is an α -methylene lactam. As noted for this class of dienophiles, the stereoselectivity results from preferred *exo* addition (see p. 471). The reaction in Entry 12 was used in an enantiospecific synthesis of estrone. The dienophile was used in enantiomerically pure form and the dioxolane ring imparts a high facial selectivity to the dienophile. The reaction occurs through an *endo* TS.

The reaction in Entry 13 is completely regioselective and both stereoisomers are formed through an *endo* TS. The two stereoisomers result from competing facial approaches to the diene.

6.1.5. Diastereoselective Diels-Alder Reactions Using Chiral Auxiliaries

The highly ordered cyclic TS of the D-A reaction permits design of diastereo- or enantioselective reactions. (See Section 2.4 of Part A to review the principles of diastereoselectivity and enantioselectivity.) One way to achieve this is to install a chiral auxiliary.⁸⁰ The cycloaddition proceeds to give two diastereomeric products that can be separated and purified. Because of the lower temperature required and the greater stereoselectivity observed in Lewis acid-catalyzed reactions, the best diastereoselectivity is observed in catalyzed reactions. Several chiral auxiliaries that are capable of high levels of diastereoselectivity have been developed. Chiral esters and amides of acrylic acid are particularly useful because the auxiliary can be recovered by hydrolysis of the purified adduct to give the enantiomerically pure carboxylic acid. Early examples involved acryloyl esters of chiral alcohols, including lactates and mandelates. Esters of the lactone of 2,4-dihydroxy-3,3-dimethylbutanoic acid (pantolactone) have also proven useful.

Ref. 81

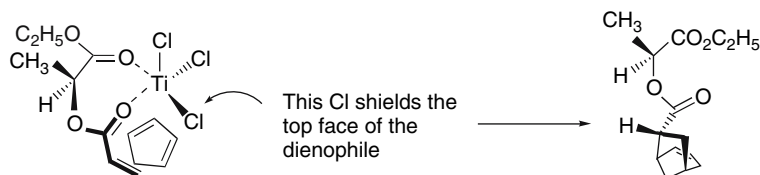

Prediction and analysis of diastereoselectivity are based on steric, stereoelectronic, and complexing interactions in the TS.⁸² In the case of the lactic acid auxiliary, a chelated structure promotes facial selectivity. In the TiCl_4 complex of *O*-acryloyl ethyl lactate,

⁸² For example, see T. Poll, A. Sobczak, H. Hartmann, and G. Helmchen, *Tetrahedron Lett.*, **26**, 3095 (1985).

one of the chlorines attached to titanium shields one face of the double bond (see also Figure 6.5).

An 8-phenylmenthol ester was employed as the chiral auxiliary to achieve enantioselectivity in the synthesis of prostaglandin precursors.⁸³ The crucial features of the TS are the *anti* disposition of the Lewis acid relative to the alcohol moiety and a π stacking with the phenyl ring that provides both stabilization and steric shielding of the α -face.

The cyclic α -hydroxylactone, pantolactone, has been used extensively as a chiral auxiliary in D-A reactions.⁸⁴ Reactions involving TiCl_4 and SnCl_4 occur through chelated TSs.⁸⁵

Several other Lewis acids including BF_3 , Et_2AlCl , and EtAlCl_2 gave somewhat reduced levels of diastereoselectivity, but still favored the chelation-controlled product.⁸⁶ However, use of two equivalents of a highly hindered monodentate Lewis acid of the MAD type favored the other diastereoisomer. These reactions are thought to proceed through an open 2:1 complex exhibiting the opposite facial selectivity.

⁸⁶ R. Maruoka, M. Oishi, and H. Yamamoto, *Synlett*, 683 (1993).

For the diester of fumaric acid, EtAlCl_2 was the most effective catalyst and the reaction proceeded with more than 90% diastereoselectivity.⁸⁷

$\text{R}^* = (\text{R})\text{-Pantolactone}$

Mandelate and lactate esters have been found to generate diastereoselectivity in reactions of hydroxy-substituted quinodimethanes generated by thermolysis of benzocyclobutenols.⁸⁸ The reactions are thought to proceed by an *exo* TS with a crucial hydrogen bond between the hydroxy group and a dienophile carbonyl. The phenyl (or methyl in the case of lactate) group promotes facial selectivity.

Several aspects of this reaction are intriguing. Despite the relatively high temperature (105°C), the nine-membered ring seems to have a strong influence on the stereoselectivity. The tendency for planarity at the ester bond may also contribute to the stability of the TS.

α, β -Unsaturated derivatives of chiral oxazolidinones have proven to be especially useful chiral auxiliaries for D-A additions. Reaction occurs at low temperatures in the presence of Lewis acids. The most effective catalyst for this system is $(\text{C}_2\text{H}_5)_2\text{AlCl}$.⁸⁹

⁸⁷. G. Helmchen, A. F. A. Hady, H. Hartmann, R. Karge, A. Krotz, K. Sartor, and M. Urmann, *Pure Appl. Chem.*, **61**, 409 (1989).

⁸⁸. D. E. Bogucki and J. L. Charlton, *J. Org. Chem.*, **60**, 588 (1995); J. L. Charlton and S. Maddaford, *Can. J. Chem.*, **71**, 827 (1993).

⁸⁹. D. A. Evans, K. T. Chapman, and J. Bisaha, *J. Am. Chem. Soc.*, **110**, 1238 (1988).

The highest level of enantioselectivity is obtained using 1.5–2.0 equivalents of $(\text{C}_2\text{H}_5)_2\text{AlCl}$. Under these conditions the reactions are thought to proceed through a chelated TS having the vinyl substituent in the *s-cis*-conformation. For oxazolidinones having *S*-configuration at C(4) of the ring, this structure exposes the *si* face at the α -carbon of the dienophile.

This complex is formed with more than 1.0 equivalents of $(\text{C}_2\text{H}_5)_2\text{AlCl}$ with concomitant formation of $[\text{Et}_2\text{AlCl}_2]^-$. The open and chelated structures have been characterized by NMR.⁹⁰ The chelated structure is substantially *more reactive* than the open complex, which accounts for the increase in enantioselectivity with more than 1.0 equivalents of catalyst.

Chelation alone, however, is not sufficient to induce high enantioselectivity since other Lewis acids capable of chelation, such as SnCl_4 and TiCl_4 , give lower enantioselectivity.

Scheme 6.3 gives some other examples of use of chiral auxiliaries in D-A reactions.⁹¹ Entries 1 and 2 show two chiral auxiliaries developed from terpene precursors. The acrylate shown in Entry 1 gave excellent enantioselectivity with cyclopentadiene and 1,3-butadiene, but introduction of a methyl substituent on the dienophile (crotonyl derivative) resulted in a very slow reaction owing to steric problems. The sulfonamide auxiliary shown in Entry 2 has been exploited in other contexts (see, e.g., p. 123). The acyl derivatives give very good facial selectivity and are thought to react through a chelated TS. The carbocyclic ring establishes facial selectivity.

g. K. Miyaji, Y. Ohara, Y. Takahashi, T. Tsuruda, and K. Arai, *Tetrahedron Lett.*, **32**, 4557 (1991).

Entry 3 involves another sultam auxiliary. The chirality of the product is consistent with approach of the diene from the *re* face of a conformation in which the carbonyl oxygen is *syn* to the sulfonyl group.

Entry 4 shows a carbohydrate-derived auxiliary with SnCl_4 as the Lewis acid. This dienophile also gives good enantioselectivity using TiCl_4 as the Lewis acid. Entry 5 is a proline-derived oxazolidinone auxiliary used in conjunction with ZrCl_4 . The observed diastereoselectivity is consistent with a chelated TS having an *s-cis* conformation at the carbonyl group.

Entry 6 uses a chiral auxiliary derived from pyroglutamic acid. Entry 7 is an example of the use of pantolactone as a chiral auxiliary to form a prostaglandin precursor.

The alkenyl oxonium ion dienophiles generated from dioxolanes can be made diastereoselective by use of chiral diols. For example, acetals derived from *anti*-pentane-2,4-diol react under the influence of $\text{TiCl}_4/\text{Ti}(i\text{-OPr})_4$ with stereoselectivity ranging from 3:1 to 15:1.

Ref. 92

Dioxolanes derived from *syn*-1,2-diphenylethane-1,2-diol react with dienes such as cyclopentadiene and isoprene, but in most cases the diastereoselectivity is low.

Ref. 93

⁹³. A. Haudrechy, W. Picoul, and Y. Langlois, *Tetrahedron: Asymmetry*, **8**, 129 (1997).

Enantioselectivity can also be achieved with chiral catalysts. The chiral oxazaborolidinones introduced in Section 2.1.5.6 as enantioselective aldol addition catalysts have been found to be useful in D-A reactions. The tryptophan-derived catalyst **A** can achieve 99% enantioselectivity in the cycloaddition between 5-benzyloxymethyl-1,3-cyclopentadiene and 2-bromopropenal. The indole ring provides π stacking and steric shielding. There is also believed to be a *formyl hydrogen bond* to the ring oxygen. A significant feature of this reaction is that the product is *exo* with respect to the formyl group. The adduct can be converted to an important intermediate for the synthesis of prostaglandins.⁹⁴

The oxazaborolidinones **B** and **C** derived from proline are also effective catalysts. The protonated forms of these catalysts, generated using triflic acid or triflimide, are very active catalysts,⁹⁵ and the triflimide version is more stable above 0°C . Another protonated catalyst **D** is derived from 2-cyclopentenylacetic acid.

α , β -Unsaturated aldehydes react via TS **E**, whereas α , β -unsaturated ketones and esters react via TS **F**.

With trisubstituted benzoquinones and use of the cationic oxazaborolidinium catalyst **B**, 2-[*tris*-(isopropyl)silyloxy]-1,3-butadiene reacts at the monosubstituted quinone double bond. The reactions exhibit high regioselectivity and more than 95% e.e. With 2-mono- and 2,3-disubstituted quinones, reaction occurs at the unsubstituted double bond. The regiochemistry is directed by coordination to the catalyst at the more basic carbonyl oxygen.

The enantioselectivity is consistent with a TS in which the less-substituted double bond of the quinone is oriented toward the catalyst, as in TS **G**.

These catalysts have been applied to D-A reactions that are parts of several important synthetic routes, thereby making them enantioselective.⁹⁶ For example, key intermediates in the synthesis of cortisone and coriolin were prepared in enantiomerically pure form using catalyst **B**.

⁹⁶ Q.-Y. Hu, G. Zhou, and E. J. Corey, *J. Am. Chem. Soc.*, **126**, 13708 (2004).

Similarly, an enantioselective synthesis of estrone is based on catalyst **D**.⁹⁷

A valine-derived oxazaborolidine derivative has been found to be subject to activation by Lewis acids, with SnCl_4 being particularly effective.⁹⁸ This catalyst combination also has reduced sensitivity to water and other Lewis bases.

Catalyst **H** and the corresponding *N*-(1-naphthylmethyl) derivative **I** give high e.e. and good *endo* stereoselectivity for several typical dienophiles with cyclopentadiene.

Cationic oxazaborolidines derived from α,α -diphenylpyrrolidine-2-methanol have been examined and shown to considerably extend the range of dienophiles that are responsive to the catalysts.⁹⁹ The best proton source for activation of these catalysts is triflimide, $(\text{CF}_3\text{SO}_2)_2\text{NH}$.¹⁰⁰ For example, cyclohexenone and cyclopentadiene react with 93% enantioselectivity using catalyst **J**.

Another cyclic boron catalyst **K**, derived from *trans*-2-aminocyclohexanemethanol, can be prepared with a quaternary nitrogen that enhances activity.¹⁰¹ This particular catalyst is not very stable, but it is highly active.

Another useful group of catalysts for D-A reactions is made up of Cu^{2+} chelates of *bis*-oxazolines.¹⁰² The copper salts are the most effective of the first transition metal series because they offer both strong Lewis acid activation and fast ligand exchange. The anion is also important and must be noncoordinating. The triflates can be used, but the hexafluoroantimonates are even more active.¹⁰³ These catalysts have been applied to dienophiles with two donor sites, in particular *N*-acyloxazolidinones. The chelated structures provide strong facial differentiation, as shown in Figure 6.9.¹⁰⁴ Installing chirality into the oxazolidinone results in matched and mismatched combinations. In addition to the *t*-butyl derivative, the 4-isopropyl-5,5-phenyl derivatives have also been explored.¹⁰⁵ The *bis*-oxazolines derived from *cis*-2-aminoindanol have also proven to be effective catalysts.¹⁰⁶ Various solid-supported forms of these BOX catalysts have been developed.¹⁰⁷

Ref. 108

The related PyBOX ligands incorporate a pyridine ring that provides an additional coordination site and are tridentate. The Sc^{3+} and lanthanide ions with the PyBOX ligand can accommodate seven to nine donors. In these complexes, the enantioselectivity is influenced by the number and identity of the coordinating species.¹⁰⁹ Figure 6.10 shows examples of a monohydrated Sc^{3+} triflate¹¹⁰ having seven contacts and a tetrahydrated lanthanide cation with a total of nine contacts, including two triflate anions.¹¹¹

The basis of the enantioselectivity of the BOX catalysts has been probed using B3LYP/6-31G* calculations.¹¹² It has been proposed that in the case of the *t*-butyl

derivatives, catalyst activity and enantioselectivity are governed by the degree to which solvent or anions can approach the copper ion. The most active catalysts are those in which nucleophilic coordination is restricted by a *t*-butyl group.

Several catalysts for enantioselective D-A reactions are based on BINOL. For example, additions of *N*-acryloyloxazolidinones can be made enantioselective using

$\text{Sc}(\text{O}_3\text{SCF}_3)_3$ in the presence of a BINOL ligand.¹¹³ Optimized conditions involved use of 5–20 mol % of the catalyst along with a hindered amine such as *cis*-1,2,6-trimethylpiperidine. A hexacoordinate TS in which the amine is hydrogen bonded to the BINOL has been proposed.

Enantioselective D-A reactions of acrolein are also catalyzed by 3-(2-hydroxyphenyl) derivatives of BINOL in the presence of an aromatic boronic acid. The optimum boronic acid is 3,5-di-(trifluoromethyl)benzeneboronic acid, with which more than 95% e.e. can be achieved. The TS is believed to involve Lewis acid complexation of the boronic acid at the carbonyl oxygen and hydrogen bonding with the hydroxy substituent. In this TS π - π interactions between the dienophile and the hydroxybiphenyl substituent can also help to align the dienophile.¹¹⁴

Dienophile	Yield (%)	<i>exo:endo</i>	e.e. (%)
$\text{CH}_2=\text{CHCH}=\text{O}$	84	3:97	95
$\text{CH}_2=\text{CCH}=\text{O}$	99	90:10	>99
$\text{E}-\text{CH}_3\text{CH}(\text{Br})=\text{CHCH}=\text{O}$	94	10:90	95
$\text{E}-\text{PhCH}=\text{CHCH}=\text{O}$	94	26:74	80

BINOL has also been used in conjunction with Ti(IV). (*S*)-BINOL- TiCl_2 provided an enantiomerically enriched starting material in the synthesis of (–)colombiasin A.¹¹⁵

BINOL in conjunction with $\text{TiCl}_2(\text{O}-i\text{-Pr})_2$ gives good enantioselectivity in a D-A reaction with a pyrone as the diene.¹¹⁶ This is a case of an inverse electron demand reaction and the catalysts would be complexed to the diene.

The $\alpha,\alpha,\alpha,\alpha$ -tetraaryl-1,3-dioxolane-4,5-dimethanol (TADDOL) chiral ligands have also been the basis of enantioselective catalysis of the D-A reaction. In a study using 2-methoxy-6-methylquinone as the dienophile, evidence was found that the chloride-ligated form of the catalysts was more active than the dimeric oxy-bridged form.¹¹⁷

A computational study [B3LYP/3-21G(*d*)] examined a related aspect of the mechanism of TADDOL- TiCl_2 catalysis of reactions with *N*-acryloyloxazolidinone.¹¹⁸ The TS model does not address the steric shielding provided by the ligand substituents but rather the role of the coordination geometry at Ti. The results of this study suggest that the reaction may proceed through a *nonminimum energy complex*. Three different TSs corresponding to different coordination geometries of the ligands were characterized, as shown in Figure 6.11. Although complex MA is lowest in energy, MB has the lowest LUMO. This structure places the exocyclic carbonyl *trans* to a chloride. The authors suggest that it may therefore be the *most reactive complex*. This issue

has not been resolved, but there is some experimental evidence that the reaction may proceed through a minor complex.¹¹⁹

Visual models and additional information on Asymmetric Diels-Alder Reactions can be found in the Digital Resource available at: Springer.com/carey-sundberg.

These examples serve to illustrate several general points about use of chiral catalysts for D-A reactions. A cationic metal center is present in nearly all of the catalysts developed to date and has several functions. It is the anchor for the chiral ligands and also serves as a Lewis acid with respect to the dienophile. The chiral ligands establish the facial selectivity of the complexed dienophile. There are several indications of the importance of the anions to catalytic activity. Anions, in general,

¹¹⁹. D. Seebach, R. Dahinden, R. E. Marti, A. K. Beck, D. A. Plattner, and F. N. M. Kuhnle, *J. Org. Chem.*, **60**, 1788 (1995); D. Seebach, R. E. Marti, and T. Hinterman, *Helv. Chim. Acta*, **79**, 710 (1996); C. Haase, C. R. Sarko, and M. Di Mare, *J. Org. Chem.*, **60**, 1777 (1995).

can compete for the ligand binding sites on the metal so that catalytic activity is improved with weakly coordinating anions. Finally, there are some indications in the TADDOL-type catalysts that the anions may exert electronic effects and serve to distinguish between reactivity of dienophiles in *cis* or *trans* positions in the octahedral coordination complex.

Several examples of catalytic enantioselective D-A reactions are given in Scheme 6.4. Entries 1 to 6 involve *N*-acyloxazolidinones and *N*-acylthiazolidinones as dienophiles. Note that there are no stereogenic centers in the reactants, so racemic mixtures would result from reaction in the absence of a chiral catalyst. The metal ions used in these reactions can accommodate two additional ligands in addition to those present in the catalyst. The reactions are believed to involve a chelated TS similar to those involved when chiral oxazolidinone are used (see p. 509). The catalyst in Entry 1 has a BOX-type ligand. The phenyl substituents and the tetrahedral coordination geometry at magnesium give rise to a well-defined geometry. Note that the catalyst has c_2 symmetry. The phenyl substituents cause differential facial shielding.

The enantioselectivity of this catalyst, which is prepared as the iodide salt, is somewhat dependent on the anion that is present. If AgSbF_6 is used as a cocatalyst, the iodide is removed by precipitation and the e.e. increases from 81 to 91%. These results indicate that the absence of a coordinating anion improved enantioselectivity. Entry 2 shows the extensively investigated *t*-BuBOX ligand with an *N*-acryloylthiazolidinone dienophile. With Cu^{2+} as the metal, the coordination geometry is square planar. The complex exposes the *re* face of the dienophile.

Entry 3 involves a catalyst derived from (*R,R*)-*trans*-cyclohexane-1,2-diamine. The square planar Cu^{2+} complex exposes the *re* face of the dienophile. As with the BOX catalysts, this catalyst has c_2 symmetry.

Entry 4 is a BOX-type catalyst derived from *cis*-1-aminoindan-2-ol. This is a somewhat more rigid ligand than the monocyclic BOX ligands. The chiral ligands in Entries 5 to 7 are TADDOLS (see p. 512) derived from tartaric acid. In Entry 5 the catalyst is prepared from $\text{TiCl}_2(\text{O-}i\text{-Pr})_2$ and 4A molecular sieves. About 0.10 equivalent of the catalyst is used. In Entry 6, the catalyst was prepared using $\text{Ti}(\text{O-}i\text{-Pr})_4$ and SiCl_4 . In this catalyst, the aryl groups carry 3,5-dimethyl groups. The 3,5-di- CF_3 and 3,5-di-Cl derivatives, which were also studied, gave high *exo:endo* ratios, but much reduced enantioselectivity. This is thought to be due to the reduced π donor character of the rings with EWG substituents. As mentioned on p. 513, the presence of chlorides at the Ti center is also probably an important factor in the reactivity of the catalyst.

Entry 7 features a quinone dienophile. The reaction exhibits the expected selectivity for the more electrophilic quinone double bond (see p. 506). The reaction is also regioselective with respect to the diene, with the methyl group acting as a donor substituent. The enantioselectivity is 80%.

In this case, the catalyst was formed by premixing $\text{Ti}(\text{O-}i\text{-Pr})_4$ and TiCl_4 and adding the TADDOL ligand. These conditions also gave good regioselectivity with isoprene, although the e.e. was not as high.

Entry 8 uses a *bis*-trifluoromethanesulfonamido chelate of methylaluminum as the catalyst. As in Entry 6, the use of a 3,5-dimethylphenyl group in place of phenyl improved enantioselectivity. The *ortho*-methylphenyl substituent on the maleimide dienophile restricts the potential coordination sites at the metal center. NMR characterization of the reactant-catalyst complex suggests that reaction occurs through the TS shown below.

Entry 9 uses the oxaborazolidine catalysts discussed on p. 505 with 2-bromopropenal as the dienophile. The aldehyde adopts the *exo* position in each case, which is consistent with the proposed TS model. Entry 10 illustrates the use of a cationic oxaborazolidine catalyst. The chirality is derived from *trans*-1,2-diaminocyclohexane. Entry 12 shows the use of a TADDOL catalyst in the construction of the steroid skeleton. Entry 13 is an intramolecular D-A reaction catalyzed by a Cu-*bis*-oxazoline. Entries 14 and 15 show the use of the oxazaborolidinone catalyst with more complex dienes.

6.1.7. Intramolecular Diels-Alder Reactions

Intramolecular Diels-Alder (IMDA) reactions are very useful in the synthesis of polycyclic compounds.¹²⁰ The stereoselectivity of a number of IMDA reactions has been analyzed and conformational factors in the TS often play the dominant role in determining product structure.¹²¹ It has also been noted in certain systems that the stereoselectivity is influenced by the activating substituent on the dienophile double bond, both for thermal and Lewis acid-catalyzed reactions.¹²² The general trends in regioselectivity are in agreement with frontier orbital concepts, with conformational effects being the main factors in determining stereoselectivity. Since the conformational interactions depend on the substituent pattern in the specific case, no general rules for stereoselectivity can be put forward. Molecular modeling can frequently identify the controlling structural features.¹²³

It is possible to introduce substituents that can influence the conformational equilibria to favor a particular product. In the reactions shown below, the addition of the trimethylsilyl substituent leads to a single stereoisomer in 85% yield, whereas in the unsubstituted system two stereoisomers are formed in ratios from 4:1 to 8:1.¹²⁴

¹²⁴ R. K. Boeckman, Jr., and T. E. Barta, *J. Org. Chem.*, **50**, 3421 (1985).

Similarly, the 2,8,10-triene **3a** gives a mixture of four isomers, but introduction of a TMS group as in **3b** gives a single stereoisomer in 89% yield. The reason for the improved stereoselectivity is that the steric effect introduced by the TMS substituent favors a single conformer.

Lewis acid catalysis usually substantially improves the stereoselectivity of IMDA reactions, just as it does in intermolecular cases. For example, the thermal cyclization of **4** at 160°C gives a 50:50 mixture of two stereoisomers, but the use of $(\text{C}_2\text{H}_5)_2\text{AlCl}$ as a catalyst permits the reaction to proceed at room temperature and *endo* addition is favored by 7:1.¹²⁵

There has been quite thorough study of 3,5-hexadienyl acrylates, where the ester functions both as part of the link and an activating substituent. The reaction tends to be quite slow, even though at first glance it would appear to encounter little strain. The *cis* ring juncture is favored by 9:1.

Ref. 126

¹²⁶ S. F. Martin, S. A. Williamson, R. P. Gist, and K. M. Smith, *J. Org. Chem.*, **48**, 5170 (1983).

One factor that is believed to contribute to the sluggishness of the reaction is that a chairlike arrangement of the linking group causes a twist in the ester group from the preferred planarity. The TS also requires that the ester alkyl group be in an *anti* relationship to the carbonyl group, rather than the preferred *syn* conformation. Several substituted systems have been studied and they react primarily through a boatlike *endo* TS.¹²⁷ The size of the α -substituent R controls the degree of preference for the TS.

This system has been studied computationally at the B3LYP/6-31 + G* level.¹²⁸ In agreement with the experimental results, the *endo* boat TS was found to be the most stable. The *endo* chair and *exo* boat were about 1.3 kcal/mol higher in energy, and the *exo* chair still higher. This study confirmed that the boatlike TS allows the ester group to stay closer to planarity. Eclipsing interactions also contribute to the higher energy of the chairlike TS. In accordance with the idea that a bidentate Lewis acid might both effect Lewis acid catalysis and promote a planar geometry at the ester group, it was found that the reaction could be effectively catalyzed by a bidentate Lewis acid.¹²⁹ Use of one equivalent of the catalyst gave 95% yield after 2 h at 0° C. The catalyst is believed to be coordinated with both the carbonyl and the ester oxygens.

Some examples of IMDA reactions are given in Scheme 6.5. In Entry 1 the dienophilic portion bears a carbonyl substituent and cycloaddition occurs easily. Two stereoisomeric products are formed, but both have the *cis* ring fusion, which is the stereochemistry expected for an *endo* TS, with the major diastereomer being formed from the TS with an equatorial isopropyl group.

In Entry 2 a similar triene that lacks the activating carbonyl group undergoes reaction but a much higher temperature is required. In this case the ring junction is *trans*, which corresponds to an *exo* TS and may reflect the absence of secondary orbital interaction between the diene and dienophile.

In Entry 3 the dienophilic double bond bears an EWG substituent, but a higher temperature is required than for Entry 1 because the connecting chain contains one less methylene group, which leads to a more strained TS. A mixture of stereoisomers is formed, reflecting a conflict between the Alder rule, which favors *endo* addition, and conformational factors, which favor the *exo* TS. The reaction in Entry 4 was carried out as a key step in the synthesis of the frog neurotoxin, pumiliotoxin C. The isolated double bond has no activating substituents and the reaction requires forcing conditions. Nevertheless, the yield is excellent and both products are formed with a *cis* ring juncture, but there is minimal facial selectivity. In Entry 5, the diene system is generated in situ by thermal elimination of the sulfoxide group and then reacts with the acetylenic dienophile.

Entry 6 shows a stereoselective formation of a highly substituted *trans*-decalin system. The reaction in Entry 7 establishes a taxanelike structure. The stereochemistry is consistent with a TS in which both the carbonyl oxygen and the methoxy group are coordinated to aluminum.

The reaction in Entry 8 was used in the synthesis of members of the phomoidrides. The cyclohexene ring that is constructed creates a bicyclo[4.3.1]skeleton containing seven- and nine-membered rings.

Entry 9 is a Lewis acid-catalyzed example, and the major stereoisomer is formed through a TS having an *endo* orientation of the complexed formyl group. Interestingly, the thermal version of this reaction favors the *exo* stereoisomer.

Entries 10 and 11 are examples of reactions involving thermal generation of quinodimethanes. In Entry 12 a quinodimethane is generated by photoenolization and used in conjunction with an IMDA reaction to create the carbon skeleton found in the hamigerans, which are marine natural products having antiviral activity.

In Entry 13, the dioxinone ring undergoes thermal decomposition to an acyl ketene that is trapped by the solvent methanol. The resulting β -keto- γ,δ -enoate ester then undergoes stereoselective cyclization. The stereoselectivity is controlled by the preference for pseudoequatorial conformations of the C(6) and C(9) substituents.

Entry 14 forms a *trans* ring juncture with greater than 99:1 selectivity. In contrast, the thermal reaction in this case shows a 2:1 preference for the *cis* ring juncture. Evidently the Lewis acid changes the structure of the TS sufficiently that the steric effects that control the thermal reaction are diminished.

Entry 15 creates a portion of the steroid skeleton and also illustrates the use of a furan ring as a diene.

As in intermolecular reactions, enantioselectivity can be achieved in IMDA additions by use of chiral components. For example, the dioxolane ring in **5** and **6** results in TS structures that lead to enantioselective reactions.¹³⁰ The chirality in the dioxolane ring is reflected in the respective TSs, both of which have an *endo* orientation of the carbonyl group.

¹³⁰. T. Wong, P. D. Wilson, S. Woo, and A. G. Fallis, *Tetrahedron Lett.*, **40**, 7045 (1997).

Chiral catalysts (see Section 6.1.6) can also achieve enantioselectivity in IMDA reactions.

The kinetic advantages of IMDA additions can be exploited by installing temporary links (tethers) between the diene and dienophile components.¹³² After the addition reaction, the tether can be broken. Siloxy derivatives have been used in this way, since silicon-oxygen bonds can be readily cleaved by solvolysis or by fluoride ion.¹³³ The silyl group can also be used to introduce a hydroxy function by oxidation.

6.2. 1,3-Dipolar Cycloaddition Reactions

In Chapter 10 of Part A, the mechanistic classification of *1,3-dipolar cycloadditions* as concerted cycloadditions was developed. Dipolar cycloaddition reactions are useful both for syntheses of heterocyclic compounds and for carbon-carbon bond formation. Table 6.2 lists some of the types of molecules that are capable of dipolar cycloaddition. These molecules, which are called *1,3-dipoles*, have π electron systems that are isoelectronic with allyl or propargyl anions, consisting of two filled and one empty orbital. Each molecule has at least one charge-separated resonance structure with opposite charges in a 1,3-relationship, and it is this structural feature that leads to the name 1,3-dipolar cycloadditions for this class of reactions.¹³⁶

The other reactant in a dipolar cycloaddition, usually an alkene or alkyne, is referred to as the *dipolarophile*. Other multiply bonded functional groups such as imine, azo, and nitroso can also act as dipolarophiles. The 1,3-dipolar cycloadditions involve four π electrons from the 1,3-dipole and two from the dipolarophile. As in the D-A reaction, the reactants approach one another in parallel planes to permit interaction between the π and π^* orbitals.

Mechanistic studies have shown that the TSs for 1,3-dipolar cycloadditions (1,3-DCA) are not very polar, the rate of reaction is not strongly sensitive to solvent polarity, and in most cases the reaction is a concerted $[2\pi_s + 4\pi_s]$ cycloaddition.¹³⁷ The destruction of charge separation that is implied is more apparent than real because

¹³⁷ P. K. Kadaba, *Tetrahedron*, **25**, 3053 (1969); R. Huisgen, G. Szeimes, and L. Mobius, *Chem. Ber.*, **100**, 2494 (1967); P. Scheiner, J. H. Schomaker, S. Deming, W. J. Libbey, and G. P. Nowack, *J. Am. Chem. Soc.*, **87**, 306 (1965).

most 1,3-dipolar compounds are not highly polar. The polarity implied by any single structure is balanced by other contributing structures.

6.2.1. Regioselectivity and Stereochemistry

Two issues are of essential for predicting the structure of 1,3-DCA products: (1) What is the regiochemistry? and (2) What is the stereochemistry? Many specific examples demonstrate that 1,3-dipolar cycloaddition is a stereospecific *syn* addition with respect to the dipolarophile, as expected for a concerted process.

Ref. 138

Ref. 139

With some 1,3-dipoles, two possible stereoisomers can be formed by *syn* addition. These result from two differing orientations of the reacting molecules that are analogous to the *endo* and *exo* TS in D-A reactions. Phenyldiazomethane, for example, can add to unsymmetrical dipolarophiles to give two diastereomers.

Ref. 140

Each 1,3-dipole exhibits a characteristic regioselectivity toward different types of dipolarophiles. The dipolarophiles can be grouped, as were dienophiles, depending upon whether they have ERG or EWG substituents. The regioselectivity can be

¹³⁸ R. Huisgen, M. Seidel, G. Wallbillich, and H. Knupfer, *Tetrahedron*, **17**, 3 (1965).

¹³⁹ R. Huisgen and G. Szeimies, *Chem. Ber.*, **98**, 1153 (1965).

¹⁴⁰ R. Huisgen and P. Eberhard, *Tetrahedron Lett.*, 4343 (1971).

interpreted in terms of frontier orbital theory. Depending on the relative orbital energies in the 1,3-dipole and dipolarophile, the strongest interaction may be between the HOMO of the dipole and the LUMO of the dipolarophile or vice versa. Usually for dipolarophiles with EWGs the dipole-HOMO/dipolarophile-LUMO interaction is dominant. The reverse is true for dipolarophiles with ERG substituents. In some circumstances the magnitudes of the two interactions may be comparable.¹⁴¹ When HOMO-LUMO interactions control regioselectivity, the reaction is said to be under *electronic control*. If steric effects are dominant, the reaction is under *steric control*.

The prediction of regiochemistry requires estimation or calculation of the energies of the orbitals that are involved, which permits identification of the frontier orbitals. The energies and orbital coefficients for the most common dipoles and dipolarophiles have been summarized.¹⁴¹ Figure 10.15 of Part A gives the orbital coefficients of some representative 1,3-dipoles. Regioselectivity is determined by the preference for the orientation that results in bond formation between the atoms having the largest coefficients in the two frontier orbitals. This analysis is illustrated in Figure 6.12.

Apart from the role of substituents in determining regioselectivity, several other structural features affect the reactivity of dipolarophiles. Strain increases reactivity; norbornene, for example, is consistently more reactive than cyclohexene in 1,3-DCA reactions. Conjugated functional groups usually increase reactivity. This increased reactivity has most often been demonstrated with electron-attracting substituents, but for some 1,3-dipoles, enol ethers, enamines, and other alkenes with donor substituents are also quite reactive. Some reactivity data for a series of alkenes with several 1,3-dipoles are given in Table 10.6 of Part A. Additional discussion of these reactivity trends can be found in Section 10.3.1 of Part A.

Fig. 6.12. Prediction of regioselectivity of 1,3-dipolar cycloaddition on the basis of FMO theory. The energies of the HOMO and LUMO of the reactants (in eV) are indicated in parentheses.

¹⁴¹ K. N. Houk, J. Sims, B. E. Duke, Jr., R. W. Strozier, and J. K. George, *J. Am. Chem. Soc.*, **95**, 7287 (1973); I. Fleming, *Frontier Orbitals and Organic Chemical Reactions*, Wiley, New York, 1977; K. N. Houk, in *Pericyclic Reactions*, Vol. II, A. P. Marchand and R. E. Lehr, eds., Academic Press, New York, 1977, pp. 181–271.

1,3-Dipoles can be embedded in heterocyclic structures, just as diene units are present in pyrones and other ring structures (see p. 491). N-Substituted pyridinium-3-ols can be deprotonated to give 3-oxidopyridinium betaines that have 1,3-dipolar character.¹⁴²

A reaction of this type was used to prepare an intermediate in the synthesis of a natural compound with antiglaucoma activity.¹⁴³

Oxazolium oxides, which can be generated by cyclization of α -amido acids, give pyrroles on reaction with acetylenic dipolarophiles.¹⁴⁴ These reactions proceed by formation of oxazolium oxide intermediates. The bicyclic adduct can then undergo a concerted (retro 4 + 2) decarboxylation.

Oxazolium oxides can also be made by N-alkylation of oxazolinones.¹⁴⁵

Pyrroles are also formed from dipolarophiles such as α -acetoxy esters and α -chloroacrylonitrile that have potential leaving groups.

Ref. 147

Another interesting variation of the 1,3-dipolar cycloaddition involves generation of 1,3-dipoles from three-membered rings. As an example, aziridines **7** and **8** give adducts derived from apparent formation of 1,3-dipoles **9** and **10**, respectively.¹⁴⁸

The evidence for the involvement of 1,3-dipoles as discrete intermediates includes the observation that the reaction rates are independent of dipolarophile concentration. This fact indicates that the ring opening is the rate-determining step in the reaction. Ring opening is most facile for aziridines that have an electron-attracting substituent to stabilize the carbanion center in the dipole.

6.2.2. Synthetic Applications of Dipolar Cycloadditions

1,3-DCA reactions are an important means of synthesis of a wide variety of heterocyclic molecules, some of which are useful intermediates in multistage syntheses. Pyrazolines, which are formed from alkenes and diazo compounds, for example, can be pyrolyzed or photolyzed to give cyclopropanes.

Scheme 6.6 gives some examples of 1,3-DCA reactions. Entry 1 is an addition of an aryl azide to norbornene. The EWG nitro group is rate enhancing and the reaction occurs with a rate constant of $6.3 \times 10^{-3} \text{ M}^{-1} \text{ s}^{-1}$ at 25°C . Owing to steric approach control, the product is the *exo* stereoisomer. Entry 2 involves an acetylenic dipolarophile and gives an aromatic triazole as the product. Entry 3 is an addition of diazomethane to the dioxolane derivative of acrolein. The reaction is carried out in a closed vessel at room temperature. Entry 4 involves a nitron as the 1,3-dipole. Nitron cycloadditions are particularly useful in synthesis because a new carbon-carbon bond is formed and the adducts can be reduced to β -amino alcohols. Nitron oxides, which are formed by dehydration of nitroalkanes or by oxidation of oximes with hypochlorite,¹⁵¹ are also useful 1,3-dipoles. They are highly reactive, must be generated in situ,¹⁵² and react with both alkenes and alkynes. The product in Entry 5 is an example in an isoxazole that was eventually converted to a prostaglandin derivative.

Intramolecular 1,3-dipolar cycloadditions have proven to be especially useful in synthesis.¹⁵³ The products of nitron-alkene cycloadditions are isoxazolines and the oxygen-nitrogen bond can be cleaved by reduction, leaving both an amino and hydroxy function in place. A number of imaginative syntheses have employed this strategy. Entry 6 shows the formation of a new six-membered carbocyclic ring. The nitron **11** is generated by condensation of the aldehyde group with *N*-methylhydroxylamine and then goes on to product by intramolecular cycloaddition.

These reactions are highly stereoselective, provided a substituent is present at C(3). The stereochemistry is consistent with a chairlike TS having the 3-substituent in an equatorial position.

Entry 7 is another intramolecular nitron cycloaddition, but in this case the hydroxylamine function is present in the alkene.

The product of the reaction in Entry 8 was used in the synthesis of the alkaloid pseudotropine. The proper stereochemical orientation of the hydroxy group is determined by the structure of the oxazoline ring formed in the cycloaddition. Entry 9 portrays the early stages of synthesis of the biologically important molecule biotin. The reaction in Entry 10 was used to establish the carbocyclic skeleton and stereochemistry of a group of toxic indolizidine alkaloids found in dart poisons from frogs. Entry 11 involves generation of a nitrile oxide. Three other stereoisomers are possible. The observed isomer corresponds to approach from the less hindered convex face of the molecule.

6.2.3. Catalysis of 1,3-Dipolar Cycloaddition Reactions

The role of Lewis acid catalysts in 1,3-DCA reactions is similar to that in D-A reactions. The catalysis results from a lowering of the LUMO energy of the dipolarophile, which is analogous to the Lewis acid catalysis of D-A reactions. The more organized TS, incorporating the metal ion and associated ligands, then enforces a preferred orientation of the reagents. In contrast to the D-A reaction involving hydrocarbon dienes, 1,3-DCA reactions may encounter competing complexation at the 1,3-dipole. Lewis acid interaction with the 1,3-dipole is likely to be detrimental if the dipole is the more nucleophilic component of the reaction. For example, with nitrones and enones, formation of a Lewis acid adduct with the nitrone in competition with the enone is detrimental. One approach to the need for selectivity is to use highly substituted catalysts that are selective for the less-substituted reactant. Bulky aryloxyaluminum compounds are excellent catalysts for nitrone cycloaddition and also enhance regioselectivity. The reaction of diphenylnitrone with enones is usually subject to steric regiochemical control. With the catalyst **L** high *electronic regiochemical control* is achieved and reactivity is greatly enhanced. The catalyst does not, however, strongly affect the *exo:endo* selectivity, which is 23:77 for propenal.

Lithium perchlorate and lithium triflate in acetonitrile catalyze intramolecular cycloaddition reactions of nitrones of allyloxybenzaldehydes and unsaturated aldehydes.¹⁵⁴

¹⁵⁴. J. S. Yadav, B. V. S. Reddy, D. Narsimhaswamy, K. Narsimulu, and A. C. Kumar, *Tetrahedron Lett.*, **44**, 3697 (2003).

A series of similar reactions was examined in the course of synthesis of substituted chromanes.¹⁵⁵ The reactions are thought to proceed through TS **M** in preference to **N** because of steric interactions with the phenyl ring on the chiral hydroxylamine.

The best Lewis acid found was $\text{Zn}(\text{OTf})_2$, which improved stereoselectivity from 6:1 to 22:1.

Interestingly, the reactions were modestly *slower* in the presence of the Lewis acid. It is suggested that the catalyst inverts the HOMO-LUMO relationships, making the complexed nitronium the electrophilic reactant. In agreement with this interpretation, the reaction is favored by EWGs on the aromatic ring.

As with D-A reactions, it is possible to achieve enantioselective cycloaddition in the presence of chiral catalysts.¹⁵⁶ Many of the catalysts are similar to those used in enantioselective D-A reactions. The catalysis usually results from a lowering of the LUMO energy of the dipolarophile, which is analogous to the Lewis acid catalysis of D-A reactions. The more organized TS, incorporating a metal ion and associated

ligands, then enforces a preferred orientation of the reagents. For example, the bulky aryl groups in the catalysts **O** and **P** favor one direction of approach of the nitronitrone reactant.¹⁵⁷

The Ti(IV) TADDOL catalyst **Q** leads to moderate enantioselectivity in nitronitrone-alkene cycloaddition.¹⁵⁸

Favorable results have also been achieved using PyBOX type catalysts. Acryloyl and crotonoyloxazolidinones gave 80–95% yields, 90–98% e.e., and more than 9:1 *endo*-diastereoselectivity in reactions with *N*-phenylbenzylidene nitrones.¹⁵⁹

Other effective enantioselective catalysts include Yb(OTf)₃ with BINOL,¹⁶⁰ Mg²⁺-*bis*-oxazolines,¹⁶¹ and oxazaborolidinones.¹⁶²

Scheme 6.7 shows some other examples of enantioselective catalysts. Entry 1 illustrates the use of a Co(III) complex, with the chirality derived from the diamine ligand. Entry 2 is a silver-catalyzed cycloaddition involving generation of an azomethine ylide. The ferrocenylphosphine groups provide a chiral environment by coordination of the catalytic Ag⁺ ion. Entries 3 and 4 show typical Lewis acid catalysts in reactions in which nitrones are the electrophilic component.

6.3. [2 + 2] Cycloadditions and Related Reactions Leading to Cyclobutanes

As discussed in Section 10.4 of Part A, concerted suprafacial [2π + 2π] cycloadditions are forbidden by orbital symmetry rules. Two types of [2 + 2] cycloadditions are of synthetic value: addition reactions of ketenes and photochemical additions. The latter group includes reactions of alkenes, dienes, enones, and carbonyl compounds, and these additions are discussed in the sections that follow.

[2 + 2] Cycloadditions of ketenes and alkenes have synthetic utility for the preparation of cyclobutanones.¹⁶³ The stereoselectivity of ketene-alkene cycloaddition can be analyzed in terms of the Woodward-Hoffmann rules.¹⁶⁴ To be an allowed process, the $[2\pi + 2\pi]$ cycloaddition must be suprafacial in one component and antarafacial in the other. An alternative description of the TS is a $2\pi_s + (2\pi_s + 2\pi_s)$ addition.¹⁶⁵ Figure 6.13 illustrates these combinations. Note that both representations predict formation of the *cis*-substituted cyclobutanone.

Ketenes are especially reactive in [2 + 2] cycloadditions and an important reason is that they offer a low degree of steric interaction in the TS. Another reason is the electrophilic character of the ketene LUMO. As discussed in Section 10.4 of Part A, there is a large net charge transfer from the alkene to the ketene, with bond formation at the ketene *sp* carbon running ahead of that at the *sp*² carbon. The stereoselectivity of ketene cycloadditions is the result of steric effects in the TS. Minimization of interaction between the substituents R and R' leads to a cyclobutanone in which these substituents are *cis*, which is the stereochemistry usually observed in these reactions.

Fig. 6.13. HOMO-LUMO interactions in the [2 + 2] cycloadditions of an alkene and a ketene: (a) frontier orbitals of the alkene and ketene; (b) $[2\pi_s + 2\pi_a]$ representation of suprafacial addition to the alkene and antarafacial addition to the ketene; (c) $[2\pi_s + (2\pi_s + 2\pi_s)]$ alignment of orbitals.

Ref. 166

The best yields are obtained when the ketene has an electronegative substituent, such as halogen. Simple ketenes are not very stable and must usually be generated *in situ*. The most common method for generating ketenes for synthesis is by dehydrohalogenation of acyl chlorides. This is usually done with an amine such as triethylamine.¹⁶⁷ Other activated carboxylic acid derivatives, such as acyloxypyridinium ions, have also been used as ketene precursors.¹⁶⁸ Ketene itself and certain alkyl derivatives can be generated by pyrolysis of carboxylic anhydrides.¹⁶⁹

Intramolecular ketene cycloadditions are possible if the ketene and alkene functionalities can achieve an appropriate orientation.¹⁷⁰

Ref. 171

Some trends in relative reactivity for intramolecular ketene cycloadditions have been examined by internal competitions.¹⁷² For example, **12** gives exclusively **13**, pointing to a preference for five-membered rings over six-membered ones.

When two different aryl substituents are compared, the double bond with an ERG substituent is more reactive, as would be expected if the alkene acts primarily as an electron donor.

¹⁷² G. Belanger, F. Levesque, J. Paquet, and G. Barbe, *J. Org. Chem.*, **70**, 291 (2005).

Comparison of *E*- and *Z*-double bonds indicates that the former are about 30 times more reactive.¹⁷³

This relative reactivity results from larger steric interactions in the TS for the *Z*-double bond.

The competition between formation of bicyclo[3.2.0] and bicyclo[3.1.1] products is determined by substitution on the alkene.

Initial bond formation occurs between the ketene carbonyl and the more nucleophilic end of the alkene double bond. This is related to the charge separation in the TS and results in the second bond being formed between the terminal ketene carbon and the carbon that is best able to support positive character.¹⁷⁴

Scheme 6.8 gives some examples of ketene-alkene cycloadditions. In Entry 1, dimethylketene was generated by pyrolysis of the dimer, 2,2,4,4-tetramethylcyclobutane-1,3-dione and passed into a solution of the alkene maintained at 70°C. Entries 2 and 3 involve generation of chloromethylketene by dehydrohalogenation of α -chloropropanoyl chloride. Entry 4 involves formation of dichloroketene. Entry 5 is an intramolecular addition, with the ketene being generated from a 2-pyridyl ester. Entries 6, 7, and 8 are other examples of intramolecular ketene additions.

Cyclobutanes can also be formed by nonconcerted processes involving zwitterionic intermediates. The combination of an electron-rich alkene (enamine, enol ether) and an electrophilic one (nitro- or polycyanoalkene) is required for such processes.

Two examples of this reaction type are shown below.

The stereochemistry of these reactions depends on the lifetime of the dipolar intermediate, which, in turn, is influenced by the polarity of the solvent. In the reactions of enol ethers with tetracyanoethylene, the stereochemistry of the enol ether is retained in nonpolar solvents. In polar solvents, cycloaddition is nonstereospecific, as a result of a longer lifetime for the zwitterionic intermediate.¹⁷⁷

Lewis acid catalysis has been used to promote stepwise $[2 + 2]$ cycloaddition of silyl enol ethers and unsaturated esters.¹⁷⁸ The best catalyst is $(\text{C}_2\text{H}_5)_2\text{AlCl}$ and polyfluoroalkyl esters give the highest stereoselectivity. The reactions give the more stable *trans* products.

6.3.2. Photochemical Cycloaddition Reactions

6.3.2.1. Photocycloaddition of Alkenes and Dienes. Photochemical cycloadditions provide a method that is often complementary to thermal cycloadditions with regard to the types of compounds that can be prepared. The theoretical basis for this complementary relationship between thermal and photochemical modes of reaction lies in orbital symmetry relationships, as discussed in Chapter 10 of Part A. The reaction types permitted by photochemical excitation that are particularly useful for synthesis are [2 + 2] additions between two carbon-carbon double bonds and [2 + 2] additions of alkenes and carbonyl groups to form oxetanes. Photochemical cycloadditions are often not concerted processes because in many cases the reactive excited state is a triplet. The initial adduct is a triplet 1,4-diradical that must undergo spin inversion before product formation is complete. Stereospecificity is lost if the intermediate 1,4-diradical undergoes bond rotation faster than ring closure.

Intermolecular photocycloadditions of alkenes can be carried out by photosensitization with mercury or directly with short-wavelength light.¹⁷⁹ Relatively little preparative use has been made of this reaction for simple alkenes. Dienes can be photosensitized using benzophenone, butane-2,3-dione, and acetophenone.¹⁸⁰ The photodimerization of derivatives of cinnamic acid was among the earliest photochemical reactions to be studied.¹⁸¹ Good yields of dimers are obtained when irradiation is carried out in the crystalline state. In solution, *cis-trans* isomerization is the dominant reaction.

The presence of Cu(I) salts promotes intermolecular photocycloaddition of simple alkenes. Copper(I) triflate is especially effective.¹⁸² It is believed that the photoreactive species is a 2:1 alkene:Cu(I) complex in which the two alkene molecules are brought together prior to photoexcitation.¹⁸³

Intramolecular [2 + 2] photocycloadditions of alkenes is an important method of formation of compounds containing four-membered rings.¹⁸⁴ Direct irradiation of simple nonconjugated dienes leads to cyclobutanes.¹⁸⁵ Strain makes the reaction unfavorable for 1,4-dienes but when the alkene units are separated by at least two carbon atoms cycloaddition becomes possible.

Ref. 186

Copper(I) triflate can facilitate these intramolecular additions, as is the case for intermolecular reactions.

Ref. 187

The most widely exploited photochemical cycloadditions involve irradiation of dienes in which the two double bonds are fairly close and result in formation of polycyclic cage compounds. Some examples of alkene photocyclizations are given in Scheme 6.9. Entry 1 is a transannular cyclization. The preference for the observed product over tricyclo[4.2.0.0^{2,5}]octane does not seem to have been analyzed in detail. Entries 2, 3, and 4 involve photolysis in the presence of CuO_3SCF_3 . Entries 5 and 6 are cases in which the double bonds are in close proximity and can cyclize to caged structures.

6.3.2.2. Photocycloaddition Reactions of Enones. Cyclic α,β -unsaturated ketones are another class of molecules that undergo photochemical cycloadditions.¹⁸⁸ The reactive

excited state is a π - π^* triplet of the enone. The reaction is most successful with cyclopentenones and cyclohexenones. The excited states of acyclic enones and larger ring compounds are rapidly deactivated by *cis-trans* isomerization and do not readily add to alkenes. Photoexcited enones can also add to alkynes.¹⁸⁹ Unsymmetrical alkenes can undergo two regioisomeric modes of addition. It is generally observed that alkenes with donor groups are oriented such that the substituted carbon becomes bound to the β -carbon, whereas with acceptor substituents the other orientation is preferred.¹⁹⁰

¹⁸⁹. R. L. Cargill, T. Y. King, A. B. Sears, and M. R. Willcott, *J. Org. Chem.*, **36**, 1423 (1971); W. C. Agosta and W. W. Lowrance, *J. Org. Chem.*, **35**, 3851 (1970).

The photoadditions proceed through 1,4-diradical intermediates. Trapping experiments with hydrogen atom donors indicate that the initial bond formation can take place at either the α - or β -carbon of the enone. The excited enone has its highest nucleophilic character at the β -carbon. The initial bond formation occurs at the β -carbon for electron-poor alkenes but at the α -carbon for electron-rich alkenes.¹⁹¹ Selectivity is low for alkenes without strong donor or acceptor substituents.¹⁹² The final product ratio also reflects the rate and efficiency of ring closure relative to fragmentation of the biradical.¹⁹³

Other structural factors can influence regioselectivity. Comparison of 2-propenol, 3-butenol, and 4-pentenol in various solvents suggests that hydrogen bonding can orient the reactants.¹⁹⁴ The reversal of regioselectivity between hexane and methanol suggests that the hydrogen bonding effects are swamped in the hydroxylic solvent methanol.

Intramolecular enone-alkene cycloadditions are also possible. In the case of β -(5-pentenyl) substituents, there is a general preference for *exo*-type cyclization to form a five-membered ring.¹⁹⁵ This is consistent with the general pattern for radical cyclizations and implies initial bonding at the β -carbon of the enone.

Ref. 195c

Scheme 6.10 gives some examples of enone cycloaddition reactions. The reaction in Entry 1 was done by direct irradiation ($\lambda > 290\text{ nm}$) in benzene. No regiochemical issues arise and the cyano group does not change the course of the reaction. The reaction in Entry 2 was used to construct [4.2.2]propellane, and was done at low temperature. The reaction in Entry 3 presumably occurs by initial bonding at the β -carbon. The preference for the *syn* orientation of the cyclohexane ring appears to be due to a steric interaction with the isopropyl group. The closure of the cyclobutane ring shows little stereoselectivity, resulting in a 2:1 mixture of stereoisomers.

The stereochemistry of the adduct formed in Entry 4 is evidently *cis* at the cyclopentane ring but it is not clear if the cyclobutane ring is *syn* or *anti*. The reaction in Entry 6 gave a mixture of stereoisomers that was subjected to reductive elimination of the vicinal dichloride. The reaction in Entry 7 exhibited complete facial stereoselectivity based on the convex shape of the ring and the presence of the methyl group on the concave face. Entries 8 to 13 are intramolecular additions that generate polycyclic rings. The reaction in Entry 8 was used in the synthesis of longifolene, a tricyclic terpene. Entry 9 gave a single stereoisomer that was used in the synthesis of a sesquiterpene, isocomene. Entry 10 was part of a synthetic route to [5.5.5.4]fenestrane. The fenestranes are tetracyclic compounds that share a central carbon. The reaction in Entry 11 was used in the synthesis of a nitrogenous terpene, incarvilline. In Entry 12, a furan ring is involved in the photocyclization. The stereochemistry seems to be determined by the reactant conformation. Other conformations of the reactant have more destabilizing steric interactions.

6.3.2.3. Photocycloaddition Reactions of Carbonyl Compounds and Alkenes. Photocycloaddition of ketones and aldehydes with alkenes can result in formation of four-membered cyclic ethers (oxetanes), a process often referred to as the *Paterno-Buchi reaction*.¹⁹⁶

The reaction is stereospecific for at least some aliphatic ketones but not for aromatic carbonyls.¹⁹⁷ This result suggests that the reactive excited state is a singlet for aliphatics and a triplets for aromatics. With aromatic ketones, the regioselectivity of addition can usually be predicted on the basis of formation of the more stable of the two possible diradical intermediates obtained by bond formation between oxygen and the alkene.¹⁹⁸

Ref. 200c

Some other examples of Paterno-Buchi reactions are given in Scheme 6.11.

6.4. [3,3]-Sigmatropic Rearrangements

The mechanistic basis of sigmatropic rearrangements was introduced in Chapter 10 of Part A. The sigmatropic process that is most widely applied in synthesis is the [3,3]-sigmatropic rearrangement. The principles of orbital symmetry establish that concerted [3,3]-sigmatropic rearrangements are allowed processes. Stereochemical predictions and analyses are based on the cyclic transition structure for a concerted reaction mechanism. Some of the various [3,3]-sigmatropic rearrangements that are used in synthesis are presented in outline form in Scheme 6.12.²⁰¹ We discuss these reactions in succeeding sections.

6.4.1. Cope Rearrangements

The Cope rearrangement is the conversion of a 1,5-hexadiene derivative to an isomeric 1,5-hexadiene by the [3,3]-sigmatropic mechanism. For unstrained compounds, the reaction occurs in the range of 150°–250° C. The reaction is both stereospecific and stereoselective. It is stereospecific in that a *Z*- or *E*-configurational relationship at either double bond is maintained in the TS and governs the relative configuration at the newly formed single bond in the product.²⁰² However, the relationship depends on the conformation of the TS. When a chair TS is favored the *E,E*- and *Z,Z*-dienes lead to *anti*-3,4-diastereomers, whereas the *E,Z*- and *Z,E*-isomers give the 3,4-*syn* product. TS conformation also determines the stereochemistry of the new double bond. If both *E*- and *Z*-stereoisomers are possible for the product, the product ratio reflects product (and TS) stability. The *E*-arrangement is normally favored for the newly formed double bonds. The stereochemical aspects of the Cope rearrangements for simple acyclic reactants are consistent with a chairlike TS in which the larger substituent at C(3) [or C(4)] adopts an equatorial-like conformation.

Owing to the concerted mechanism, chirality at C(3) [or C(4)] leads to enantiospecific formation of new stereogenic centers formed at C(1) [or C(6)].²⁰³ These relationships are illustrated in the example below. Both the configuration of the new stereocenter and the new double bond are those expected on the basis of a chairlike TS. Since there are two stereogenic centers, the double bond and the asymmetric carbon, there are four possible stereoisomers of the product. Only two are formed. The *E*-double bond isomer has the *S*-configuration at C(4) and the *Z*-isomer has the *R*-configuration. These are the products expected for a chair TS. The stereochemistry of the new double bond is determined by the relative stability of the two chair TSs. TS **B** is less favorable than **A** because of the axial placement of the larger phenyl substituent.

The products corresponding to boatlike TSs are usually not observed for acyclic dienes. However, this TS is allowed and if steric factors make a boat TS preferable to a chair, reaction can proceed through a boat. Thermochemical²⁰⁴ and computational²⁰⁵ studies indicate that the boat TS is intrinsically 6–10 kcal/mol higher in energy. Reactions that proceed through a boat TS have the reverse stereochemical relationships between the configuration at the stereogenic center and the double bond.

Cope rearrangements are reversible reactions and, as there is no change in the number or types of bonds as a result of the reaction, to a first approximation the total bond energy is unchanged. The position of the final equilibrium is governed by the relative stability of the starting material and product. In the example cited above, the equilibrium is favorable because the product is stabilized by conjugation of the alkene with the phenyl ring.

When ring strain is relieved, Cope rearrangements can occur at much lower temperatures and with complete conversion to ring-opened products. A striking example is the conversion of *cis*-divinylcyclopropane to 1,4-cycloheptadiene, a reaction that occurs readily below -40°C .²⁰⁶

Several transition metal ions and complexes, especially Pd(II) salts, have been found to catalyze Cope rearrangements.²⁰⁷ The catalyst that has been adopted for synthetic purposes is $\text{PdCl}_2(\text{CH}_3\text{CN})_2$, and with it the rearrangement of **14** to **15** and **16** occurs at room temperature, as contrasted to 240°C in its absence.²⁰⁸ The catalyzed reaction shows enhanced stereoselectivity and is consistent with a chairlike TS.

The mechanism for catalysis is formulated as a stepwise process in which the electrophilic character of Pd(II) facilitates the bond formation.²⁰⁹

When there is a hydroxy substituent at C(3) of the diene system, the Cope rearrangement product is an enol that is subsequently converted to the corresponding

carbonyl compound. This is called the *oxy-Cope rearrangement*.²¹⁰ The formation of the carbonyl compound provides a net driving force for the reaction.²¹¹

An important improvement in the oxy-Cope reaction was made when it was found that the reaction is strongly catalyzed by base.²¹² When the C(3) hydroxy group is converted to its alkoxide, the reaction is accelerated by a factor of 10^{10} – 10^{17} . These base-catalyzed reactions are called *anionic oxy-Cope rearrangements*, and their rates depend on the degree of cation coordination at the oxy anion. The reactivity trend is $K^+ > Na^+ > Li^+$. Catalytic amounts of tetra-*n*-butylammonium salts lead to accelerated rates in some cases. This presumably results from the dissociation of less reactive ion pair species promoted by the tetra-*n*-butylammonium ion.²¹³

The stereochemistry of acyclic anionic oxy-Cope rearrangements is consistent with a chair TS having a conformation that favors equatorial placement of both alkyl and oxy substituents and minimizes the number of 1,3-diaxial interactions.²¹⁴ For the reactions shown below, the double-bond configuration is correctly predicted on the basis of the most stable TS available in the first three reactions. In the fourth reaction, the TSs are of comparable energy and a 2:1 mixture of *E*- and *Z*-isomers is formed.

Silyl ethers of vinyl allyl alcohols can also be used in oxy-Cope rearrangements.²¹⁵ Known as the *siloxo-Cope rearrangement*, this methodology has been used in

connection with *syn*-selective aldol additions in stereoselective synthesis.²¹⁶ The use of the silyloxy group prevents reversal of the aldol addition, which would otherwise occur under anionic conditions. The reactions proceed at convenient rates at 140°–180° C.

Ref. 217

Ref. 218

Scheme 6.13 gives some examples of Cope and oxy-Cope rearrangements. Entry 1 shows a reaction that was done to compare the energy of chair and boat TSs. The chiral diastereomer shown can react through a chair TS and has a ΔG^* about 8 kcal/mol lower than the *meso* isomer, which must react through a boat TS. The equilibrium is biased toward product by the fact that the double bonds in the product are more highly substituted, and therefore more stable, than those in the reactant.

Entry 2 illustrates the reversibility of the Cope rearrangement. In this case, the equilibrium is closely balanced with the reactant benefiting from a more-substituted double bond, whereas the product is stabilized by conjugation. The reaction in Entry 3 involves a *cis*-divinylcyclopropane and proceeds at much lower temperature than the previous examples. The reaction was used in the preparation of an intermediate for the synthesis of pseudoguiane-type natural products.

Entries 4 and 5 illustrate the use of the oxy-Cope rearrangement in formation of medium-size rings. The *trans*-double bond in the product for Entry 4 arises from a chair TS.

The reaction in Entry 5 is a case in which the thermal conditions were preferable to the basic conditions because of the base sensitivity of the product. Entries 6 to 10 show anionic oxy-Cope reactions. Entries 6 and 7 are early examples of the application of the reaction in synthesis. Entries 8 and 9 involve rearrangements of bicyclo[2.2.1]hept-2-en-2-ol derivatives to give *cis*-fused bicyclo[4.3.0]non-7-en-3-ones.

The rearrangement in Entry 9 occurs spontaneously on warming of the reaction mixture from addition of an organolithium reagent to form the vinyl carbinol unit. This is a very general means of constructing reactants for oxy-Cope rearrangements that leads

to carbon-carbon bond formation between C(2) of the vinyl lithium reagent and C(4) of the β,γ -enone.

The reaction in Entry 10 demonstrated that a vinyl substituent in conjugation with the vinyl carbinol accelerates rearrangement. The reaction was considerably more facile than the corresponding reaction with a saturated isopropyl group. The reaction in Entry 11 was used in the synthesis of terpene derivatives. Entries 12 and 13 are examples of the siloxy-Cope version of the reaction. These entries illustrate the utility of the oxy-Cope reaction in the synthesis of ring systems. Some of these transformations may be difficult to recognize, at least at first glance. The retrosynthetic transformation can be recognized by identifying the δ,ϵ -enone and locating the bond that is ruptured in the rearrangement. For example, the retrosynthetic formulation of the reaction in Entry 9 identifies the precursor.

6.4.2. Claisen and Modified Claisen Rearrangements

The basic pattern of the Claisen rearrangement is the conversion of a vinyl allyl ether to a γ,δ -enone. The reaction is also observed for allyl phenyl ethers, in which case the products are *o*-allylphenols.

There are several synthetically important adaptations of the reaction. It can be applied to orthoesters (Section 6.4.2.2) or silyl ketene acetals (Section 6.4.2.3), in which case the products are γ,δ -unsaturated acids or esters. An analogous reaction using amide

acetals gives γ,δ -unsaturated amides (Section 6.4.2.4). In all cases, the reactions occur with 1,3-transposition of the allylic group.

6.4.2.1. Claisen Rearrangements of Allyl Vinyl Ethers. The [3,3]-sigmatropic rearrangement of allyl vinyl ethers leads to γ,δ -enones and is known as the *Claisen rearrangement*.²¹⁹ The reaction is mechanistically analogous to the Cope rearrangement and occurs at temperatures above 150°C. As the product is a carbonyl compound, the equilibrium is usually favorable. The reaction introduces an α -acyl alkyl group at the γ -carbon of the allylic alcohol, with 1,3-transposition of the allylic double bond.

The reactants can be made from allylic alcohols by mercuric ion-catalyzed exchange with ethyl vinyl ether.²²⁰ The allyl vinyl ether need not be isolated and is often prepared under conditions that lead to its rearrangement. The simplest of all Claisen rearrangements, the conversion of allyl vinyl ether to 4-pentenal, typifies this process.

Ref. 221

Acid-catalyzed exchange can also be used to prepare the vinyl ethers.

Ref. 222

Vinyl ethers can also be generated by thermal elimination reactions. For example, base-catalyzed conjugate addition of allyl alcohols to phenyl vinyl sulfone generates 2-(phenylsulfinyl)ethyl ethers that can undergo elimination at 200°C.²²³ The sigmatropic

rearrangement proceeds under these conditions. Allyl vinyl ethers can also be prepared by Wittig reactions using ylides generated from allyloxymethylphosphonium salts.²²⁴

As with the Cope rearrangement, PdCl_2 can catalyze the Claisen rearrangement.

Ref. 225

However, it can also catalyze competing reactions and works best for relatively highly substituted systems.²²⁶ Catalysis of Claisen rearrangements has been achieved using highly hindered *bis*-(phenoxy)methylaluminum as Lewis acids.²²⁷ These reagents also have the ability to control the E:Z ratio of the products. Very bulky catalysts tend to favor the Z-isomer by forcing the α -substituent of the allyl group into an axial conformation.

tris-Aryloxyaluminum compounds are also effective catalysts for the Claisen rearrangement.²²⁸ When used in a 1.2 molar ratio, the rearrangement occurs at -78°C .

Some representative Claisen rearrangements are shown in Scheme 6.14. Entry 1 illustrates the application of the Claisen rearrangement in the introduction of a substituent at the junction of two six-membered rings. Introduction of a substituent at this type of position is frequently necessary in the synthesis of steroids and terpenes. In Entry 2, formation and rearrangement of a 2-propenyl ether leads to formation of a methyl ketone. Entry 3 illustrates the use of 3-methoxyisoprene to form the allylic ether. The rearrangement of this type of ether leads to introduction of isoprene structural units into the reaction product. Entry 4 involves an allylic ether prepared by O-alkylation of a β -keto enolate. Entry 5 was used in the course of synthesis of a diterpene lactone. Entry 6 is a case in which PdCl_2 catalyzes both the formation and rearrangement of the reactant.

Entry 7 illustrates reaction conditions that were applicable to formation and rearrangement of an isopropenyl allylic ether. The tri-isopropylaluminum is thought to both catalyze the sigmatropic rearrangement and reduce the product ketone.

The reaction in Entry 8 was conducted in excess refluxing vinyl *t*-butyl ether, using 1.1 equivalent of $\text{Hg}(\text{OAc})_2$ to catalyze the exchange reaction. In Entry 9 a thermal reaction leads to formation of an eight-membered ring.

Aryl allyl ethers can also undergo [3,3]-sigmatropic rearrangement. In fact, Claisen rearrangements of allyl phenyl ethers to *ortho*-allyl phenols were the first [3,3]-sigmatropic rearrangements to be thoroughly studied.²²⁹ The reaction proceeds through a cyclohexadienone that enolizes to the stable phenol.

If both *ortho*-positions are substituted, the allyl group undergoes a second migration, giving the *para*-substituted phenol:

Ref. 230

6.4.2.2. Orthoester Claisen Rearrangements. There are several variations of the Claisen rearrangement that make it a powerful tool for the synthesis of γ,δ -unsaturated carboxylic acids. The *orthoester modification of the Claisen rearrangement* allows carboalkoxymethyl groups to be introduced at the γ -position of allylic alcohols.²³¹ A mixed orthoester is formed as an intermediate and undergoes sequential elimination and sigmatropic rearrangement.

²²⁹ S. J. Rhoads, in *Molecular Rearrangements*, Vol. 1, P. de Mayo, ed., Interscience, New York, 1963, pp. 655–684.

²³⁰ I. A. Pearl, *J. Am. Chem. Soc.*, **70**, 1746 (1948).

²³¹ W. S. Johnson, L. Werthemann, W. R. Bartlett, T. J. Brocksom, T. Li, D. J. Faulkner, and M. R. Petersen, *J. Am. Chem. Soc.*, **92**, 741 (1970).

Both the exchange and elimination are catalyzed by the addition of a small amount of a weak acid, such as propanoic acid. These reactions are usually conducted at the reflux temperature of the orthoester, which is about 110°C for the trimethyl ester and 140°C for the triethyl ester. Microwave heating has been used and is reported to greatly accelerate orthoester-Claisen rearrangements.²³²

The mechanism and stereochemistry of the orthoester Claisen rearrangement is analogous to the Cope rearrangement. The reaction is stereospecific with respect to the double bond present in the initial allylic alcohol. In acyclic molecules, the stereochemistry of the product can usually be predicted on the basis of a chairlike TS.²³³ When steric effects or ring geometry preclude a chairlike structure, the reaction can proceed through a boatlike TS.²³⁴

High levels of enantiospecificity have been observed in the rearrangement of chiral reactants. This method can be used to establish the configuration of the newly formed carbon-carbon bond on the basis of the configuration of the C–O bond in the starting allylic alcohol. Treatment of (2*R*, 3*E*)-3-penten-2-ol with ethyl orthoacetate gives the ethyl ester of (3*R*, 4*E*)-3-methyl-4-hexenoic acid in 90% enantiomeric purity.²³⁵ The configuration of the new stereocenter is that predicted by a chairlike TS with the methyl group occupying a pseudoequatorial position.

Scheme 6.15 gives some representative examples of the orthoester Claisen rearrangement. Entry 1 is an example of the standard conditions for the orthoester Claisen rearrangement using triethyl orthoacetate as the reactant. The allylic alcohol is heated in an excess of the orthoester (5.75 equivalents) with 5 mol % of propanoic acid. Ethanol is distilled from the reaction mixture. The *E*-double bond arises from the chair TS.

The reaction in Entry 2, involving trimethyl orthoacetate, was effected in the course of synthesis of an insect juvenile hormone. The reaction is highly stereoselective (> 98%) for the *E*-isomer at the new double bond. The reactions in Entries 3 and 4 were used to introduce ester substituents on the nitrogen-containing rings. Note that in Entry 4 an orthobutanoate ester is used, demonstrating that longer-chain orthoesters

are suitable for the reaction and permit the synthesis of α, α -disubstituted esters. The reaction in Entry 5 was used in the synthesis of protected analogs of γ -amino acids. The reaction gave the expected *E*-double bond. The reaction in Entry 6 was used in an enantiospecific synthesis of a pumiliotoxin alkaloid. Entry 7 presents a case of chirality transfer. The *S*-allylic alcohol generates the *S*-configuration at the new C—C bond with an e.e. of more than 99%. The reaction in Entry 8 was used in the synthesis of an insect pheromone, and the triple bond was eventually reduced to a *Z*-double bond. The reaction in Entry 9 was part of enantiospecific synthesis of more complex terpenoids from *R*-carvone. Note that in this case, the cyclic TS results in introduction of the ester substituent *syn* to the hydroxy group on the ring, which is a general result for cyclic reactants.

6.4.2.3. Rearrangements of Silyl Ketene Acetals and Ester Enolates. Esters of allylic alcohols can be rearranged to γ, δ -unsaturated carboxylic acids via the *O*-trimethylsilyl ethers of the ester enolate.²³⁶ These intermediates are called *silyl ketene acetals*. This version of the reaction, known as the *Ireland-Claisen rearrangement*,²³⁷ takes place under much milder conditions than the orthoester method. The reaction occurs at room temperature or slightly above. The stereochemistry of the silyl ketene acetal Claisen rearrangement is controlled not only by the configuration of the double bond in the allylic alcohol but also by the stereochemistry of the silyl ketene acetal. The chair TS predicts that the relative configuration at the newly formed C—C bond will be determined by the *E*- or *Z*-stereochemistry of the silyl ketene acetal.

The stereochemistry of the silyl ketene acetal can be controlled by the conditions of preparation. The base that is usually used for enolate formation is lithium diisopropylamide (LDA). If the enolate is prepared in pure THF, the *E*-enolate is generated and this stereochemistry is maintained in the silyl derivative. The preferential formation of the *E*-enolate can be explained in terms of a cyclic TS in which the proton is abstracted from the stereoelectronically preferred orientation perpendicular to the carbonyl plane. The carboxy substituent is oriented away from the alkyl groups on the amide base.

If HMPA is included in the solvent, the *Z*-enolate predominates.^{236,238} DMPU also favors the *Z*-enolate. The switch to the *Z*-enolate with HMPA or DMPU is attributed to a looser, perhaps acyclic TS being favored as the result of strong solvation of the lithium ion. The steric factors favoring the *E*-TS are therefore diminished.²³⁹ These general principles of solvent control of enolate stereochemistry are applicable to other systems.²⁴⁰ For example, by changing the conditions for silyl ketene acetal formation, the diastereomeric compounds **17a** and **17b** can be converted to the same product with high diastereoselectivity.²⁴¹

A number of steric effects on the rate of rearrangement have been observed and can be accommodated by the chairlike TS model.²⁴² The *E*-silyl ketene acetals

²⁴² C. S. Wilcox and R. E. Babston, *J. Am. Chem. Soc.*, **108**, 6636 (1986).

rearrange somewhat more slowly than the corresponding *Z*-isomer. This is interpreted as resulting from the pseudoaxial placement of the methyl group in the *E*-transition structure.

The size of the substituent *R* also influences the rate, with the rate increasing somewhat for both isomers as *R* becomes larger. It is believed that steric interactions with *R* are relieved as the C–O bond stretches. The rate acceleration reflects the higher ground state energy resulting from these steric interactions.

The silyl ketene acetal rearrangement can also be carried out by reaction of the ester with a silyl triflate and tertiary amine, without formation of the ester enolate. Optimum results are obtained with bulky silyl triflates and amines, e.g., *t*-butyldimethylsilyl triflate and *N*-methyl-*N*,*N*-dicyclohexylamine. Under these conditions the reaction is stereoselective for the *Z*-silyl ketene acetal and the stereochemistry of the allylic double bond determines the *syn* or *anti* configuration of the product.²⁴³

The stereochemistry of Ireland-Claisen rearrangements of cyclic compounds is sometimes indicative of reaction through a boat TS. For example, the major product from 2-cyclohexenyl propanoate is formed through a boat TS.²⁴⁴

²⁴³. M. Kobayashi, K. Matsumoto, E. Nakai, and T. Nakai, *Tetrahedron Lett.*, **37**, 3005 (1996).

²⁴⁴. R. E. Ireland, P. Wipf, and J.-N. Xiang, *J. Org. Chem.*, **56**, 3572 (1991).

The reason for the trend toward boat TSs in cyclic systems is the introduction of additional steric factors. For example, addition of methyl and isopropenyl substituents leads to a TS in which the cyclohexene ring adopts a boat conformation, whereas the TS is chairlike.

Heteroatoms, particularly oxygen, introduce electronic factors that favor boat TSs.

Computational modeling (B3LYP/6-31G*) of rearrangement of cyclohexenol identified the four potential TS geometries shown in Figure 6.14.²⁴⁵ Using the *O*-methyl enol ether as a model, a 2-cyclohexenyl ester prefers a *syn*-boat TS, in agreement with the experimental results. As in the experimental work, the placement of additional substituents alters the relative energies of these TSs.

Fig. 6.14. Possible transition structures for [3,3]-sigmatropic rearrangement of 2-cyclohexenyl ester enol ethers. Adapted from *J. Org. Chem.*, **68**, 572 (2003), by permission of the American Chemical Society.

The stereoselectivity of silyl ketene acetal Claisen rearrangements can also be controlled by specific intramolecular interactions.²⁴⁶ The enolates of α -alkoxy esters adopt the *Z*-configuration because of chelation by the alkoxy substituent.

The configuration at the newly formed C—C bond is then controlled by the stereochemistry of the double bond in the allylic alcohol. The *E*-isomer gives a *syn* orientation, whereas the *Z*-isomer gives rise to *anti* stereochemistry.²⁴⁷

Similar chelation effects are present in α -alkoxymethyl derivatives. Magnesium enolates give predominantly the *Z*-enolate as a result of this chelation. The corresponding trimethylsilyl ketene acetals give *E,Z* mixtures.²⁴⁸

Enolates of allyl esters of α -amino acids are also subject to chelation-controlled Claisen rearrangement.²⁴⁹

Various salts can achieve chelation but ZnCl_2 and MgCl_2 are suitable for most cases. The rearrangement is a useful reaction for preparing amino acid analogs and has also been applied to synthesis of modified dipeptides.²⁵⁰

Lewis acid catalysis of Ireland-Claisen rearrangements by TiCl_4 has been observed.²⁵¹ This methodology was employed in the synthesis of a novel type of anti-inflammatory drug candidate.²⁵²

The possibility of using chiral auxiliaries or chiral catalysts to achieve enantioselective Claisen rearrangements has been explored.²⁵³ One approach is to use chiral boron enolates. For example, enolates prepared with the chiral diazaborolidine bromide **O** lead to rearranged products of more than 95% enantiomeric excess.²⁵⁴

The enantioselectivity is consistent with a chairlike TS in which the stereocenters control the rotational preference for the sulfonyl groups that provide stereodifferentiation at the boron center.

Ref. 256

Scheme 6.16 gives some examples of Ireland-Claisen rearrangements of silyl ketene acetals and related intermediates. Entry 1 is an example from an early investigation of this version of the rearrangement. Entry 2 involves direct rearrangement of the enolate without silylation. The reaction in Entry 3 was used for stereoselective synthesis of the γ , δ -unsaturated acid, which was used in the synthesis of a butterfly pheromone. The TBDMS derivative gave a somewhat higher yield than the TMS derivative in this case. The reaction in Entry 4 was used in the conversion of carbohydrate-derived starting materials to structures found in ionophore antibiotics. The reaction conditions, which involved use of *premixed* LDA and TMS-Cl, were designed to avoid a competing β -elimination of the enolate by rapid silylation of the enolate.

In Entry 5, the chirality at an alkylated succinate ester is maintained and a 9:1 dr favoring the *anti* product is achieved, based on a preferred orientation relative to the branched substituent.

Entry 6 is an example of application of the chiral diazaborolidine enolate method (see p. 572). Entry 7 involves generation of the silyl ketene acetal by silylation after conjugate addition of the enolate of 3-methylbutanoyloxazolidinone to allyl 3,3,3-trifluoroprop-2-enoate. A palladium catalyst improved the yield in the rearrangement

step. Entry 8 involves another fluorinated reactant. The reaction is an adaptation of the rearrangement of α -amido ester enolates, as discussed on p. 572, and involves a chelated enolate. Entry 9 is another example of this type of reaction. Use of quinine or quinidine with the chelating metal leads to enantioselectivity.

Entries 10 to 15 involve use of the Ireland-Claisen rearrangement in multistep syntheses. An interesting feature of Entry 11 is the presence of an unprotected ketone. The reaction was done by adding LDA to the ester, which was premixed with TMS-Cl and Et₃N. The reaction generates the *E*-silyl ketene acetal, which rearranges through a chair TS.

Entries 12 to 15 are examples of α -alkoxy (protected glycolate) esters. These reactions proceed through chelated TSs. (See the discussion on p. 571.) The TS for Entries 13 and 14 are shown below.

Entry 15 also demonstrates the suprafacial specificity with a cyclic allylic alcohol.

6.4.2.4. Claisen Rearrangements of Ketene Aminals and Imidates. A reaction that is related to the orthoester Claisen rearrangement utilizes an amide acetal, such as dimethylacetamide dimethyl acetal, in the exchange reaction with allylic alcohols.²⁵⁷ The products are γ, δ -unsaturated amides. The stereochemistry of the reaction is analogous to the other variants of the Claisen rearrangement.²⁵⁸

²⁵⁸. W. Sucrow, M. Slopianka, and P. P. Calderia, *Chem. Ber.*, **108**, 1101 (1975).

The rearrangement can be applied to other secondary amines by prior equilibration, which is driven forward by removal of the more volatile dimethylamine.²⁵⁹

O-Allyl imidate esters undergo [3,3]-sigmatropic rearrangements to *N*-allyl amides. Trichloromethyl imidates can be made easily from allylic alcohols by reaction with trichloroacetoneitrile. The rearrangement then provides trichloroacetamides of *N*-allylamines.²⁶⁰

Yields in the reaction are sometimes improved by inclusion of K_2CO_3 in the reaction mixture.²⁶¹

Trifluoromethyl imidates show similar reactivity.²⁶² Imidate rearrangements are catalyzed by palladium salts.²⁶³ The mechanism is presumably similar to that for the Cope rearrangement (see p. 555).

Chiral Pd catalysts can achieve enantioselectivity. The best catalysts developed to date are dimeric ferrocenyl derivatives.²⁶⁴

²⁶⁴. Y. Donde and L. E. Overman, *J. Am. Chem. Soc.*, **121**, 2933 (1999).

Imidate esters can also be generated by reaction of imidoyl chlorides and allylic alcohols. The lithium anions of these imidates, prepared using lithium diethylamide, rearrange at around 0°C. When a chiral amine is used, this reaction can give rise to enantioselective formation of γ, δ -unsaturated amides. Good results were obtained with a chiral binaphthylamine.²⁶⁵ The methoxy substituent is believed to play a role as a Li^+ ligand in the reactive enolate.

Enolates of *N*-allyl amides undergo [3,3]-sigmatropic rearrangement. This reaction is analogous to the ester enolate Claisen rearrangement, but the conditions required are more vigorous.²⁶⁶ An attractive feature of this reaction is that it permits introduction of a chiral group at nitrogen, which then has the potential to effect enantioselective formation of a new C–C bond. For example, α -arylethyl substituents induced enantioselectivity ranging from 3:1 to 11:1.

Analogous rearrangement occurs under much milder conditions when the reactant is a zwitterion generated by deprotonation of an acylammonium ion. Substituted pyrrolidines were used as the chiral auxiliary, with the highest enantioselectivity being achieved with a 2-TBDMS derivative.²⁶⁷

The preferred TS is a chair with the enolate oriented *syn* to the bulky pyrrolidine substituent. It was suggested that the *syn* acylation occurs through an envelope conformation of the pyrrolidine ring with the nitrogen electron pair oriented axially.

²⁶⁵ P. Metz and B. Hungerhoff, *J. Org. Chem.*, **62**, 4442 (1997).

²⁶⁷ S. Laabs, W. Munch, J.-W. Bats, and U. Nubbemeyer, *Tetrahedron*, **58**, 1317 (2002).

Another promising variant involves thioamides, which provide *Z*-thioenolates on deprotonation.²⁶⁸ Use of *trans*-2,4-diphenylpyrrolidine as the chiral auxiliary leads to good enantioselectivity.²⁶⁹ Allyl groups with *E*-configuration give mainly *anti* products with somewhat reduced diastereoselectivity. These results indicate that a steric interaction between the pyrrolidine substituent and the *Z*-allyl group is a controlling factor in diastereoselectivity.

The 2-azonia analog of the Cope rearrangement is estimated to be accelerated by 10^6 , relative to the unsubstituted system.²⁷⁰ The product of the rearrangement is an isomeric iminium ion, which is a mild electrophile. In synthetic applications, the reaction is often designed to generate this electrophilic site in a position that can lead to a cyclization by reaction with a nucleophilic site. For example, the presence of a 4-hydroxy substituent generates an enol that can react with the iminium ion intermediate to form a five-membered ring.²⁷¹

Scheme 6.17 gives some examples of the orthoamide and imidate versions of the Claisen rearrangement. Entry 1 applied the reaction in the synthesis of a portion of the alkaloid tabersonine. The reaction in Entry 2 was used in an enantiospecific synthesis of pravastatin, one of a family of drugs used to lower cholesterol levels. The product from the reaction in Entry 3 was used in a synthesis of a portion of the antibiotic rampamycin. Entries 4 and 5 were used in the synthesis of polycyclic natural products. Note that the reaction in Entry 4 also leads to isomerization of the double bond into conjugation with the ester group. Entries 1 to 5 all involve cyclic reactants, and the concerted TS ensures that the substituent is introduced *syn* to the original hydroxy substituent.

Entry 6 is analogous to a silyl ketene acetal rearrangement. The reactant in this case is an imide. Entry 7 is an example of PdCl_2 -catalyzed imidate rearrangement. Entry 8 is an example of an azonia-Cope rearrangement, with the monocyclic intermediate then undergoing an intramolecular Mannich condensation. (See Section 2.2.1 for a discussion of the Mannich reaction). Entry 9 shows a thioimide rearrangement.

6.5. [2,3]-Sigmatropic Rearrangements

The [2,3]-sigmatropic class of rearrangements is represented by two generic charge types, neutral and anionic.

The rearrangements of allylic sulfoxides, selenoxides, and amine oxides are an example of the first type. Allylic sulfonium ylides and ammonium ylides also undergo [2,3]-sigmatropic rearrangements. Rearrangements of carbanions of allylic ethers are the major example of the anionic type. These reactions are considered in the following sections.

6.5.1. Rearrangement of Allylic Sulfoxides, Selenoxides, and Amine Oxides

The rearrangement of allylic sulfoxides to allylic sulfenates was first studied in connection with the mechanism of racemization of allyl aryl sulfoxides.²⁷² Although the allyl sulfoxide structure is strongly favored at equilibrium, rearrangement through the achiral allyl sulfenate provides a low-energy pathway for racemization.

²⁷². R. Tang and K. Mislow, *J. Am. Chem. Soc.*, **92**, 2100 (1970).

The reactions occur preferentially through an *endo* TS in which the sulfur substituent is oriented toward the allylic group.²⁷³ Computational studies (MP2/6-31G*) found the *endo* TS to be favored over the *exo* by 1.5–2.2 kcal/mol.²⁷⁴

The allyl sulfonate–allyl sulfonate rearrangement can be used to prepare allylic alcohols.²⁷⁵ The reaction is carried out in the presence of a reagent, such as phenylthiolate or trimethyl phosphite, that reacts with the sulfonate to cleave the S–O bond.

An analogous reaction occurs when allylic selenoxides are generated in situ by oxidation of allylic selenyl ethers.²⁷⁷

N-Allylamine oxides represent the general pattern for [2,3]-sigmatropic rearrangement where X = N and Y = O[−]. The rearrangement provides *O*-allyl hydroxylamine derivatives.

Rhodium catalysis have been used for formation of ylides by intramolecular reactions.

Ref. 284

Ref. 285

Ammonium ylides can also be generated when one of the nitrogen substituents has an anion stabilizing group on the α -carbon. For example, quaternary salts of *N*-allyl α -aminoesters readily rearrange to γ,δ -unsaturated α -aminoesters.²⁸⁶

Ammonium ylides can also be generated by the carbenoid route.

Ref. 287

Copper-catalyzed reactions are particularly effective with α -diazo- β -dicarbonyl compounds such as diethyl diazomalonate.

Ref. 288

Scheme 6.18 illustrates typical reaction conditions for [2,3]-sigmatropic rearrangements of sulfonium and ammonium ylides. The reactant sulfonium salt used in Entry 1 is generated by alkylation of ethyl methylthioacetate and rearrangement occurs in the presence of potassium carbonate. Entries 2 and 3 show ring-expansion reactions. The reactant in Entry 2 has no activating group and the reaction presumably proceeds through a small equilibrium concentration of the methylylide.

Entries 5 to 8 involve ammonium ylides. These reactions effect an N to C transfer of the substituent with 1,3-allylic transposition. In the case of Entry 7, the anionic stabilization is provided by a vinylogous ester group. The reaction in Entry 8 begins with N-allylation, which takes place *syn* to the ester group because of the *trans* orientation of the ester and benzyl groups, and the chirality is thereby induced at the nitrogen atom. The [2,3]-rearrangement then transfers chirality to C(2) of the pyrrolidine ring.

A useful method for *ortho*-alkylation of aromatic amines is based on [2,3]-sigmatropic rearrangement of *S*-anilinosulfonium ylides. These ylides are generated from anilinosulfonium ions, which can be prepared from *N*-chloroanilines and sulfides.²⁸⁹

This method is the basis for synthesis of nitrogen-containing heterocyclic compounds when Z is a carbonyl-containing substituent.²⁹⁰

6.5.3. Anionic Wittig and Aza-Wittig Rearrangements

The [2,3]-sigmatropic rearrangement pattern is also observed with anionic species. The most important case for synthetic purposes is the *Wittig rearrangement*, in which a strong base converts allylic ethers to α -allylalkoxides.²⁹¹ Since the deprotonation at the α' -carbon must compete with deprotonation of the α -carbon in the allyl group, most examples involve a conjugated or EWG substituent Z.²⁹²

The stereochemistry of the Wittig rearrangement can be predicted in terms of a cyclic five-membered TS in which the α -substituent prefers an equatorial orientation.²⁹³

A consistent feature of the stereoselectivity is a preference for *E*-configuration at the newly formed double bond. The reaction can also show stereoselectivity at the newly formed single bond. This stereoselectivity has been carefully studied for the case in

²⁹¹. J. Kallmarten, in *Stereoselective Synthesis: Houben Weyl Methods in Organic Chemistry*, Vol E21d, R. W. Hoffmann, J. Mulzer, and E. Schaumann, eds., G. Thieme Verlag, Stuttgart, 1996, pp. 3810 ff.

which the substituent Z is an alkynyl group. The *E*-isomer leads to *anti* product and the *Z*-isomer to the *syn* product.

The preferred TS minimizes interaction between the Z and allylic substituents. This stereoselectivity is illustrated in the rearrangement of **18** to **19**.

Ref. 294

There are other means of generating the anions of allyl ethers. One of the most useful for synthetic purposes involves a lithium-tin exchange on stannylmethyl ethers (see Section 7.1.2.4).²⁹⁵

Another means involves reduction of allylic acetals of aromatic aldehydes by SmI_2 .²⁹⁶

[2,3]-Sigmatropic rearrangements of anions of *N*-allyl amines have also been observed and are known as *aza-Wittig rearrangements*.²⁹⁷ The reaction requires anion stabilizing substituents and is favored by *N*-benzyl and by silyl or sulfonyl substituents

²⁹⁷ C. Vogel, *Synlett*, 497 (1997).

on the allyl group.²⁹⁸ The trimethylsilyl substituents can also influence the stereoselectivity of the reaction. The steric interactions between the benzyl group and allyl substituent govern the stereoselectivity and it is markedly improved in the trimethylsilyl derivatives.²⁹⁹

Some examples of synthetic application of the anionic Wittig rearrangement are given in Scheme 6.19. The reaction in Entry 1 provided a 93:7 ratio favoring the *syn* isomer, as expected for the preferred *endo* TS. Entry 2 is an example that employs the lithium-stannane exchange to generate the anion. The reaction in Entry 3 accomplishes a ring contraction. Under normal conditions, it is selective for the *trans* stereoisomer, as would be expected from steric factors in the TS. In the presence of HMPA, the *cis* isomer dominates, but the reason for the change is not known.

In Entry 4 the silyl group appears to introduce a controlling steric factor, leading to the observed stereoisomer. The unsubstituted terminal alkyne, which reacts through the dianion, gives the alternate isomer.

The stereoselectivity of the reaction in Entry 5 is also determined by steric factors. Note also that in this case the oxazoline ring serves to stabilize the anion.

6.6. Unimolecular Thermal Elimination Reactions

This section describes reactions in which elimination to form a double bond or a new ring occurs as a result of thermal activation. There are several such thermal elimination reactions that are used syntheses, some of which are concerted processes. The

activation energy requirements and stereochemistry of concerted elimination processes can be analyzed in terms of orbital symmetry considerations. Cheletropic eliminations are discussed in Section 6.6.1 and elimination of nitrogen from azo compounds in Section 6.6.2. We consider an important group of unimolecular β -elimination reactions in Section 6.6.3.

6.6.1. Cheletropic Elimination

Cheletropic processes are defined as reactions in which two bonds are broken at a single atom. Concerted cheletropic reactions are subject to orbital symmetry analysis in the same way as cycloadditions and sigmatropic processes. In the elimination processes of interest here, the atom X is normally bound to other atoms in such a way that elimination gives rise to a stable molecule. In particular, elimination of SO_2 , N_2 , or CO from five-membered 3,4-unsaturated rings can be a facile process.

A good example of a concerted cheletropic elimination is the reaction of 3-pyrroline with *N*-nitrohydroxylamine, which gives rise to the diazene **21**, which then undergoes elimination of nitrogen.

Use of substituted systems has shown that the reaction is stereospecific.³⁰⁰ The groups on C(2) and C(5) of the pyrroline ring rotate in the disrotatory mode on going to product. This stereochemistry is consistent with conservation of orbital symmetry.

The most synthetically useful cheletropic elimination involves 2,5-dihydrothiophene-1,1-dioxides (sulfolene dioxides). At moderate temperatures they fragment to give dienes and sulfur dioxide.³⁰¹ The reaction is stereospecific. For example, the dimethyl derivatives **22** and **23** give the *E,E*- and *Z,E*-isomers of 2,4-hexadiene, respectively, at temperatures of $100^\circ\text{--}150^\circ\text{C}$.³⁰² This stereospecificity corresponds to disrotatory elimination.

³⁰⁷ K. C. Nicolaou, W. E. Barnette, and P. Ma, *J. Org. Chem.*, **45**, 1463 (1980).

The elimination of carbon monoxide can occur by a concerted process in some cyclic ketones. The elimination of carbon monoxide from bicyclo[2.2.1]heptadien-7-ones is very facile. In fact, generation of bicyclo[2.2.1]heptadien-7-ones is usually accompanied by spontaneous decarbonylation.

The ring system can be generated by D-A addition of a substituted cyclopentadienone and an alkyne. A reaction sequence involving addition followed by CO elimination can be used for the synthesis of highly substituted benzene rings.³⁰⁸

Ref. 309

The synthetic utility of cyclopentadienones is limited, however, because they are quite unstable. Exceptionally facile elimination of CO also takes place from **22**, in which homoaromaticity can facilitate elimination.

Ref. 310

6.6.2. Decomposition of Cyclic Azo Compounds

Another significant group of elimination reactions involves processes in which a small molecule is eliminated from a ring system and the two reactive sites that remain re-form a ring.

The most common example is decomposition of azo compounds, where $-X-Y-$ is $-N=N-$.³¹¹ The elimination of nitrogen from cyclic azo compounds can be carried

³⁰⁸. M. A. Ogliaruso, M. G. Romanelli, and E. I. Becker, *Chem. Rev.*, **65**, 261 (1965).

³⁰⁹. L. F. Fieser, *Org. Synth.*, **V**, 604 (1973).

³¹⁰. B. A. Halton, M. A. Battiste, R. Rehberg, C. L. Deyrup, and M. E. Brennan, *J. Am. Chem. Soc.*, **89**, 5964 (1967).

³¹¹. P. S. Engel, *Chem. Rev.*, **80**, 99 (1980).

out either photochemically or thermally. Although the reaction usually does not proceed by a concerted mechanism, there are some special cases in which concerted elimination is possible. We consider these cases first and then move on to the more general case. An interesting illustration of the importance of orbital symmetry effects is the contrasting stability of azo compounds **23** and **24**. Compound **23** decomposes to norbornene and nitrogen only above 100°C. In contrast **24** eliminates nitrogen immediately on preparation, even at -78°C.³¹²

The reason for this difference is that if **23** were to undergo a concerted elimination it would have to follow the forbidden (high-energy) $[2\pi_s + 2\pi_s]$ pathway. For **24**, the elimination can take place by the allowed $[2\pi_s + 4\pi_s]$ pathway. Thus, these reactions are the reverse, respectively, of the $[2\pi_s + 2\pi_s]$ and $[2\pi_s + 4\pi_s]$ cycloadditions, and only the latter is an allowed concerted process. The temperature at which **23** decomposes is fairly typical for strained azo compounds and it presumably proceeds by a nonconcerted biradical mechanism. Since a C–N bond must be broken without concomitant compensation by carbon-carbon bond formation, the activation energy is higher than for a concerted process.

Although the concerted mechanism described in the preceding paragraph is available only to those azo compounds with appropriate orbital arrangements, the nonconcerted mechanism occurs at low enough temperatures to be synthetically useful. The elimination can also be carried out photochemically. These reactions presumably occur by stepwise elimination of nitrogen, and the ease of decomposition depends on the stability of the radical R^\cdot .

The stereochemistry of the nonconcerted reaction has been a topic of considerable study. Frequently, there is partial stereorandomization, indicating a short-lived diradical intermediate. The details vary from case to case, and both preferential inversion and retention of relative stereochemistry have been observed.

Ref. 313

³¹² N. Rieber, J. Alberts, J. A. Lipsky, and D. M. Lemal, *J. Am. Chem. Soc.*, **91**, 5668 (1969).

³¹³ R. J. Crawford and A. Mishra, *J. Am. Chem. Soc.*, **88**, 3963 (1966).

Ref. 314

These results can be interpreted in terms of competition between recombination of the diradical intermediate and conformational equilibration, which would destroy the stereochemical relationships present in the azo compound. The main synthetic application of azo compound decomposition is in the synthesis of cyclopropanes and other strained-ring systems. Some of the required azo compounds can be made by 1,3-dipolar cycloadditions of diazo compounds (see Section 6.2).

Elimination of nitrogen from D-A adducts of certain heteroaromatic rings has been useful in syntheses of substituted aromatic compounds.³¹⁵ Pyrazines, triazines, and tetrazines react with electron-rich dienophiles in inverse electron demand cycloadditions. The adducts then aromatize with loss of nitrogen and a dienophile substituent.³¹⁶

Pyridazine-3,6-dicarboxylate esters react with electron-rich alkenes to give adducts that undergo subsequent elimination to give terephthalate derivatives.³¹⁷

Similar reactions have been developed for 1,2,4-triazines and 1,2,4,5-tetrazines.

Ref. 322

6.6.3. β -Eliminations Involving Cyclic Transition Structures

Another important family of elimination reactions has as its common mechanistic feature cyclic TSs in which an intramolecular hydrogen transfer accompanies elimination to form a new carbon-carbon double bond. Scheme 6.20 depicts examples of these reaction types. These are thermally activated unimolecular reactions that normally do not involve acidic or basic catalysts. There is, however, a wide variation in the temperature at which elimination proceeds at a convenient rate. The cyclic TS dictates that elimination occurs with *syn* stereochemistry. At least in a formal sense, all the reactions can proceed by a concerted mechanism. The reactions, as a group, are often referred to as *thermal syn eliminations*.

d. H. R. Nace, *Org. React.*, **12**, 57 (1962).

Amine oxide pyrolysis occurs at temperatures of 100°–150° C. The reaction can proceed at room temperature in DMSO.³²³ If more than one type of β -hydrogen can attain the eclipsed conformation of the cyclic TS, a mixture of alkenes is formed. The product ratio parallels the relative stability of the competing TSs. Usually more of the *E*-alkene is formed because of the larger steric interactions present in the TS leading to the *Z*-alkene, but the selectivity is generally not high.

In cyclic systems, conformational effects and the requirement for a cyclic TS determine the product composition. This effect can be seen in the product ratios from pyrolysis of *N,N*-dimethyl-2-phenylcyclohexylamine-*N*-oxide.

³²³ D. J. Cram, M. R. V. Sahyun, and G. R. Knox, *J. Am. Chem. Soc.*, **84**, 1734 (1962).

In the *trans* isomer, elimination to give a double bond conjugated with an aromatic ring is especially favorable. This presumably reflects both the increased acidity of the proton α to the phenyl ring and the stabilizing effect of the developing conjugation in the TS. In the *cis* isomer there is no *syn* hydrogen at the phenyl-substituted carbon and the nonconjugated regioisomer is formed. Amine oxides can be readily prepared from amines by oxidation with hydrogen peroxide or a peroxycarboxylic acid. Some typical examples of amine oxide elimination are given in Section A of Scheme 6.21.

Sulfoxides also undergo thermal elimination reactions. The elimination tends to give β, γ -unsaturation from β -hydroxysulfoxides and can be used to prepare allylic alcohols.

Ref. 324

Sulfoxide elimination in conjunction with [2,3]-sigmatropic rearrangement has been used to convert allylic alcohols to dienes.

Ref. 325

EWG substituents promote the removal of hydrogen, and sulfoxide eliminations are particularly favorable for β -keto and similar sulfoxides.

Selenoxides are even more reactive than sulfoxides toward β -elimination. In fact, many selenoxides react spontaneously when generated at room temperature. Synthetic procedures based on selenoxide eliminations usually involve synthesis of the corresponding selenide followed by oxidation and in situ elimination. We have already discussed examples of these procedures in Section 4.3.2, where the conversion of ketones and esters to their α, β -unsaturated derivatives is considered. Selenides can

³²⁴ J. Nokami, K. Ueta, and R. Okawara, *Tetrahedron Lett.*, 4903 (1978).

³²⁵ H. J. Reich and S. Wollowitz, *J. Am. Chem. Soc.*, **104**, 7051 (1982).

also be prepared by electrophilic addition of selenenyl halides and related compounds to alkenes (see Section 4.1.6). Selenide anions are powerful nucleophiles and can displace halides or tosylates and open epoxides.³²⁶ Selenide substituents stabilize an adjacent carbanion, so α -selenenyl carbanions can be prepared. One procedure involves conversion of a ketone to a *bis*-selenoketal, which can then be cleaved by *n*-butyllithium.³²⁷ The carbanions in turn add to ketones to give β -hydroxyselenides.³²⁸ Elimination gives an allylic alcohol.

Alcohols can be converted to *o*-nitrophenylselenides by reaction with *o*-nitrophenyl selenocyanate and tri(*n*-butyl)phosphine.³²⁹

The selenides prepared by any of these methods can be converted to selenoxides by such oxidants as hydrogen peroxide, sodium metaperiodate, peroxycarboxylic acids, *t*-butyl hydroperoxide, or ozone.

Like amine oxide elimination, selenoxide eliminations normally favor formation of the *E*-isomer in acyclic structures. In cyclic systems the stereochemical requirements of the cyclic TS govern the product composition. Section B of Scheme 6.21 gives some examples of selenoxide eliminations.

Amine oxide and sulfoxide elimination TS structures have been compared by computations at the MP2/6-31G(*d*) level.³³⁰ The calculated E_a values are 26 and 33 kcal/mol, respectively. Kinetic isotope effects have also been calculated³³¹ and are in good agreement with experimental values. The experimental E_a values for sulfoxide eliminations are typically near 30 kcal/mol.³³² For aryl sulfoxides, the E_a is somewhat lower, around 25–28 kcal/mol. Several sulfoxide elimination reactions have been examined computationally.³³³ MP2/6-311+G(3*df*,2*p*) calculations gave generally good agreement with experimental values for ΔH , ΔH^\ddagger , and kinetic isotope effects.

³³² D. W. Emerson, A. P. Craig, and I. W. Potts, Jr., *J. Org. Chem.*, **32**, 102, 3725 (1967); C. Walling and L. Bollyky, *J. Org. Chem.*, **29**, 2699 (1964).

³³³ J. W. Cubbage, Y. Guo, R. D. McCulla, and W. S. Jenks, *J. Org. Chem.*, **66**, 8722 (2001).

The minimum-energy TSs are planar and the O—H and C—H bond orders were usually less than 0.4 and less than 0.5, respectively, and the S—C bond order was less than 0.5. The C—C bond order was around 1.3. The reaction can be described as a concerted intramolecular proton transfer, with the sulfoxide oxygen acting as a base and the sulfur as a leaving group.

The TS for selenoxide elimination has also been examined computationally.³³⁴ The C—H bond cleavage runs ahead of the C—Se cleavage.

A third category of *syn* eliminations involves pyrolytic decomposition of esters with elimination of a carboxylic acid. The pyrolysis of acetate esters normally requires temperatures above 400° C and is usually a vapor phase reaction. In the laboratory this is done by using a glass tube in the heating zone of a small furnace. The vapors of the reactant are swept through the hot chamber by an inert gas and into a cold trap. Similar reactions occur with esters derived from long-chain acids. If the boiling point of the ester is above the decomposition temperature, the reaction can be carried out in the liquid phase, with distillation of the pyrolysis product.

Ester pyrolysis has been shown to be a *syn* elimination in the case of formation of stilbene by the use of deuterium labels.³³⁵

Although recognizing the existence of the concerted cyclic mechanism, it has been proposed that most preparative pyrolyses proceed as surface-catalyzed reactions.³³⁶

Mixtures of alkenes are formed when more than one type of β -hydrogen is present. In acyclic compounds the product composition often approaches that expected on a statistical basis from the number of each type of hydrogen. The *E*-alkene usually predominates over the *Z*-alkene for a given isomeric pair. In cyclic structures, elimination is in the direction that the cyclic mechanism can operate most favorably.

³³⁴ N. Kondo, H. Fueno, H. Fujimoto, M. Makino, H. Nakaoka, I. Aoki, and S. Uemura, *J. Org. Chem.*, **59**, 5254 (1994).

Ref. 336

Alcohols can be dehydrated via xanthate esters at temperatures that are much lower than those required for acetate pyrolysis. The preparation of xanthate esters involves reaction of the alkoxide with carbon disulfide. The resulting salt is alkylated with methyl iodide.

The elimination is often effected simply by distillation.

Product mixtures are observed when more than one type of β -hydrogen can participate in the reaction. As with the other *syn* thermal eliminations, there are no intermediates that are prone to skeletal rearrangement.

Scheme 6.21 gives some examples of thermal elimination reactions. Entries 1 to 3 show amine-oxide decompositions. The reaction in Entry 1 shows a preference for the conjugated product. This reaction was also conducted in dry DMSO, where it was found to proceed at 25°C.³³⁸ Entry 2 illustrates the use of the reaction to prepare methylenecyclohexane. The method is particularly useful in this case because there is no tendency for competing elimination or rearrangement to the more stable 1-methylcyclohexene. Entries 4 and 5 are sulfoxide eliminations. Entry 4 is favored by the conjugation of the phenyl group and occurs under very mild conditions. The conditions for elimination in Entry 5 are more typical. Entries 6 to 9 are selenoxide eliminations. In Entries 6 and 7, the selenide group is introduced by nucleophilic substitution. In Entry 8, electrophilic selenolactonization was used to synthesize the reactant. Although the yield of the product, oxete, in Entry 9 is quite low, this was one of the first preparations of this compound. Entries 10 to 12 are high-temperature acetate pyrolyses. Entries 13 to 17 are xanthate pyrolyses. In Entry 15, the use of DMSO as the solvent for the preparation of the dialcoholate was found to be advantageous.

6.2. Intramolecular cycloaddition reactions occur under the conditions specified for each of the following reactions. Show the structures of the products of each reaction, including all aspects of stereochemistry and indicate the structure of the product-determining TS and any key intermediates.

6.3. Indicate the mechanistic type to which each of these reactions belongs and write out a mechanism showing any intermediates.

6.4. Apply retrosynthetic analysis to the following transformation and show how each of the target molecules could be prepared from the starting materials given. No more than three separate steps are needed in any of the syntheses.

- (a) 
- (b) 
- (c) 
- (d) $\text{CH}_3\text{CH}_2\text{C}\equiv\text{CCH}=\text{CHCH}_2\text{CH}_2\text{CO}_2\text{CH}_3 \Rightarrow$ propenal, 1-butyne and triethyl orthoacetate
- (e) 
- (f) 
- (g) 
- (h) 
- (i) 
- (j) 

6.5. Suggest mechanisms by which the following transformations occur.

- The addition reaction of tetracyanoethylene and ethyl vinyl ether in acetone gives 94% of a [2 + 2] adduct and 6% of an adduct having the composition tetracyanoethylene + ethyl vinyl ether + acetone. If the [2 + 2] adduct is kept in contact with acetone for several days, it is completely converted to the minor product. What is a likely structure for the minor product? How is it formed in the original reaction and on standing in acetone?
- When vinylcyclopropane is irradiated with benzophenone or benzaldehyde both oxetane and oxepene products are obtained. How are the oxepenes formed?

- A convenient preparation of 2-allylcyclohexanone involves simply heating the diallyl acetal of cyclohexanone in toluene containing a trace of *p*-toluenesulfonic acid and collecting a distillate of toluene and allyl alcohol.
 - A solution of 2-butenal, 2-acetoxypropene, and dimethyl acetylenedicarboxylate refluxed in the presence of a small amount of an acid catalyst gives an 80% yield of dimethyl phthalate.
- 6.6. The following syntheses were carried by short tandem reaction sequences starting with the Diels-Alder reaction shown. Show the reagents and approximate reaction conditions required to complete the transformation.

6.7. The ester **7-1** gives alternative stereoisomers when subjected to Claisen rearrangement as the lithium enolate or as the silyl ketene acetal. Analyze the respective transition structures and develop a rationale to explain these results.

6.8. Photolysis of **8-1** gives an isomeric compound **8-2** in 83% yield. Alkaline hydrolysis of **8-2** affords a hydroxy carboxylic acid, **8-3**, $\text{C}_{25}\text{H}_{32}\text{O}_4$. Treatment of **8-2** with silica gel in hexane yields **8-4**, $\text{C}_{24}\text{H}_{28}\text{O}_2$. **8-4** is converted by $\text{NaIO}_4\text{-KMnO}_4$ to a mixture of **8-5** and **8-6**. What are the structures of **8-2**, **8-3**, and **8-4**?

6.9. Suggest mechanisms for the following reactions that involve loss of N_2 .

a. 1,2,4,5-Tetrazines react with alkenes to give dihydropyridazines, as in the example below.

b. Compounds **9-1** and **9-2** are both unstable toward loss of nitrogen at room temperature and both give **9-3** as the product.

6.10. For each of the following reactions propose a transition structure that would account for the observed stereoselectivity. Identify important conformational and other features of the proposed transition structure.

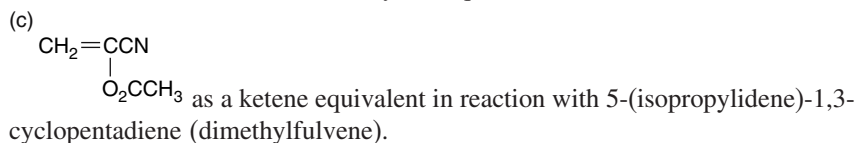

6.11. Provide an outline of the mechanisms of the following transformations.

6.12. In each part, the molecule shown was employed as a synthetic equivalent in a cycloaddition reaction. Show a sequence of reactions by which the adduct can be converted to the desired product.

- (d) $\text{CH}_2=\text{CHNO}_2$ as a ketene equivalent in reaction with 5-methoxymethyl-1,3-cyclopentadiene.

6.13. Suggest reaction sequences for accomplishing each of the following synthetic transformations.

- (a) Squalene from succinaldehyde, 2-bromopropene, and 3-methoxy-2-methyl-1,3-butadiene.

6.14. By retrosynthetic analysis, identify a precursor that could provide the desired product by a single pericyclic reaction. Indicate appropriate reaction conditions for the transformation you identify.

6.15. Predict the structure of the major product, including stereochemistry, of the following reactions. Draw the transition structures and identify the features that control the stereochemistry of the reaction.

6.16. Oxepin is in equilibrium with benzene oxide by a [3,3]-sigmatropic shift. Advantage has been taken of this equilibrium to develop a short synthesis of barrelene. Outline a way that this could be done.

6.17. The following transformations involve generation of anionic intermediates that then undergo cycloaddition reactions. Identify the anion intermediate and outline the mechanism for each transformation.

6.18. When the lactone silyl ketene acetal **18-1** is heated to 135°C a mixture of four stereoisomers is obtained. Although the major one is the expected [3,3]-sigmatropic rearrangement product, lesser amounts of other possible C(4a) and C(5) epimers are also formed. When the reaction mixture is heated to 100°C, partial conversion to the same mixture of stereoisomers is observed, but most of the product at this temperature is an acyclic triene ester. Suggest a structure for the triene ester and show how it can be formed. Discuss the significance of the observation of the triene ester for the lack of complete stereospecificity in the rearrangement.

6.19. The following cycloaddition reactions involve chiral auxiliaries and proceed with a good degree of diastereoselectivity. Provide a rationalization of the formation of the preferred product on the basis of a TS.

- 6.20. The following transformations involve two or more pericyclic reactions occurring in tandem during the process. Suggest a plausible sequence of reactions that can lead to the observed product.

- 6.21. The Diels-Alder reaction of *N*-acryloyloxazolidinone catalyzed by Cu(*t*-Bu)BOX shows a reversal of stereoselectivity between 1-acetoxybutadiene and 1-acetoxy-3-methylbutadiene. The former gives a 85:15 *endo:exo* ratio, whereas the latter is 27:73 *endo:exo*. Explain this reversal in terms of the transition structure model given on p. 509.

- 6.22. The alkenyl cyclopentenone **22a-c** have been subjected to photolysis with the results shown below. Analyze these results in terms of the mechanistic interpretation given on p. 547.

6.23. The intramolecular Diels-Alder reaction of **23-1** carried out under LiClO_4 catalysis is rather nonselective. Use a molecular mechanics program to assess the energies of the competing TSs and products. Are the results in agreement with the experimental outcome?

Organometallic Compounds of Group I and II Metals

Introduction

The use of organometallic reagents in organic synthesis had its beginning around 1900 when Victor Grignard discovered that alkyl and aryl halides react with magnesium metal to give homogeneous solutions containing organomagnesium compounds. The “Grignard reagents” proved to be highly reactive carbon nucleophiles and are still very useful synthetic reagents. Organolithium reagents came into synthetic use somewhat later, but are also very important for synthesis. The present chapter focuses on Grignard reagents and organolithium compounds. We also consider zinc, cadmium, mercury, indium, and lanthanide organometallics, which have more specialized places in synthetic methodology. Certain of the transition metals, such as copper, palladium, and nickel, which are also important in synthetic methodology, are discussed in Chapter 8.

The composition of the organolithium compounds is RLi or more accurately $(\text{RLi})_n$. The organomagnesium compounds are usually formulated as RMgX , with X being a halide. The organometallic derivatives of Group I and II metals provide reactive carbon nucleophiles. Reactivity increases in the order $\text{Li} < \text{Na} < \text{K}$ and $\text{MgX} < \text{CaX}$, but the lithium and magnesium reactions are by far the most commonly used. Organolithium and magnesium reagents react with polar multiple bonds, especially carbonyl groups, and provide synthetic routes to a variety of alcohols. Other electrophiles, such as acyl halides, nitriles, and CO_2 provide routes to ketones and carboxylic acids.

The Group IIB organometallics derived from zinc, cadmium, and mercury are considerably less reactive. The carbon-metal bonds in these compounds have more covalent character than for lithium or magnesium reagents. Zinc, cadmium, and mercury are distinct from other transition metals in having a d^{10} shell in the +2 oxidation state and their reactions usually do not involve changes in oxidation state. Although organozinc and cadmium reagents react with acyl chloride, reactions with other carbonyl compounds require either Lewis acids or chelates as catalysts. These catalyzed reactions make organozinc reagents particularly useful in additions to aldehydes. The lanthanides and indium organometallics are usually in the +3 oxidation state, which are also filled valence shells, and have a number of specialized applications that depend on their strong oxyphilic character.

7.1. Preparation and Properties of Organomagnesium and Organolithium Reagents

The compounds of lithium and magnesium are the most important of Group IA and IIA organometallics. The metals in these two groups are the most electropositive of the elements, and the polarity of the metal-carbon bond increases the electron density on carbon. This electronic distribution is responsible for the strong nucleophilicity and basicity of these compounds. There is a high ionic character in the carbon-metal bonds, but the compounds tend to exist as aggregates and have good solubility in some nonpolar solvents.

7.1.1. Preparation and Properties of Organomagnesium Reagents

The reaction of magnesium metal with an alkyl or aryl halide in diethyl ether is the standard method for synthesis of Grignard reagents. The order of reactivity of the halides is $\text{RI} > \text{RBr} > \text{RCl}$.

The formation of Grignard reagents takes place at the metal surface. Reaction commences with an electron transfer to the halide and decomposition of the radical ion, followed by rapid combination of the organic group with a magnesium ion.¹ It

Soc.*, **108**, 2490 (1986); E. C. Ashby and J. Oswald, *J. Org. Chem.*, **53**, 6068 (1988); H. M. Walborsky,

has been suggested that the reactions may involve reduction of the halide by clusters of magnesium atoms.²

Solutions of several Grignard reagents such as methylmagnesium bromide, ethylmagnesium bromide, and phenylmagnesium bromide are available commercially. Some Grignard reagents are formed more rapidly in tetrahydrofuran than in ether. This is true of vinylmagnesium bromide, for example.³ Other ether solvents such as dimethoxyethane can be used. For industrial purposes, where less volatile solvents are needed for reasons of safety, *bis*-2-butoxyethyl ether (butyl diglyme), bp 256°C, can be used. The solubility of Grignard reagents in ethers is the result of Lewis acid-base complex formation between the magnesium ion and the ether oxygens.

Under normal laboratory conditions magnesium metal is coated with an unreactive layer of Mg(OH)_2 , and the reactions do not start until the organic halide diffuses through it. The reaction appears to begin at discrete sites,⁴ and accelerates as the surface coating breaks up, exposing more active surface. The ether solvents are probably involved and may assist dissociation of the metal ions from the surface. Various techniques for initiating the reactions, such as addition of small amounts of I_2 or $\text{BrCH}_2\text{CH}_2\text{Br}$, appear to involve the generation of Mg^{2+} salts, which serve to facilitate the reaction. Sonication or mechanical pretreatment can also be used to activate magnesium.⁵ Organic halides that are unreactive toward magnesium shavings can often be induced to react by using an extremely reactive form of magnesium that is obtained by reducing magnesium salts with sodium or potassium metal.⁶ Even alkyl fluorides, which are normally unreactive, form Grignard reagents under these conditions.

One of the fundamental questions about the mechanism is whether the radical is really “free” in the sense of diffusing from the metal surface.⁷ For alkyl halides, there is considerable evidence that the radicals behave similarly to alkyl free radicals.⁸ One test for the involvement of radical intermediates is to determine whether cyclization occurs in the 6-hexenyl system, where radical cyclization is rapid (see Part A, Section 12.2.2).

Small amounts of cyclized products are obtained after the preparation of Grignard reagents from 5-hexenyl bromide.⁹ This indicates that cyclization of the intermediate radical competes to a small extent with combination of the radical with the metal. Quantitative kinetic models that compare competing processes are consistent with diffusion of the radicals from the surface.¹⁰ Alkyl radicals can be trapped with high efficiency by the nitroxide radical TMPO.¹¹ Nevertheless, there remains disagreement about the extent to which the radicals diffuse away from the metal surface.¹²

It seems likely that aryl, vinyl, and cyclopropyl halides react by an alternative mechanism, since the corresponding radicals are less stable than alkyl radicals. It has been suggested that these halides may react through a dianion.¹³

The radical cyclization test has been applied and although 2-(3-butenyl)phenyl halides give little if any cyclization, substituents that are expected to increase the rate of cyclization to around 10^9 s^{-1} do give some cyclic product.¹⁴

The stereochemistry of Grignard reagents having stereogenic centers is another means of probing the structure and lifetime of intermediates. The preparation of Grignard reagents from alkyl halides normally occurs with stereochemical randomization at the reaction site. Stereoisomeric halides give rise to organomagnesium compounds of identical composition.¹⁵ The main exceptions to this generalization are cyclopropyl and alkenyl systems, which react with partial retention of configuration.¹⁶ Once formed, secondary alkylmagnesium compounds undergo stereochemical inversion only slowly. *Endo*- and *exo*-norbornylmagnesium bromide, for example, require 1 day at room temperature to reach equilibrium.¹⁷ NMR studies have demonstrated that inversion of configuration is quite slow, on the NMR time scale, even

up to 170°C.¹⁸ In contrast, the inversion of configuration of primary alkylmagnesium halides is very fast.¹⁹ This difference in the primary and secondary systems may be the result of a mechanism for inversion that involves exchange of alkyl groups between magnesium atoms.

If bridged intermediates are involved, the larger steric bulk of secondary systems would retard the reaction. Steric restrictions may be further enhanced by the fact that organomagnesium reagents are often present as clusters (see below).

The usual designation of Grignard reagents as RMgX is a useful but incomplete representation of the composition of the compounds in ether solution. An equilibrium exists with magnesium bromide and the dialkylmagnesium.²⁰

The position of the equilibrium depends upon the solvent and the identity of the specific organic group, but in ether lies well to the left for simple aryl-, alkyl-, and alkenylmagnesium halides.²¹ Solutions of organomagnesium compounds in diethyl ether contain aggregated species.²² Dimers predominate in ether solutions of alkylmagnesium chlorides.

The corresponding bromides and iodides show concentration-dependent behavior and in very dilute solutions they exist as monomers. In tetrahydrofuran, there is less tendency to aggregate, and several alkyl and aryl Grignard reagents have been found to be monomeric in this solvent.

A number of Grignard reagents have been subjected to X-ray structure determination.²³ Ethylmagnesium bromide has been observed in both monomeric and dimeric forms in crystal structures.²⁴ Figures 7.1a and b show, respectively, the crystal structure

of the monomer with two diethyl ether molecules coordinated to magnesium and a dimeric structure with one diisopropyl ether molecule per magnesium.

7.1.2. Preparation and Properties of Organolithium Compounds

7.1.2.1. Preparation Using Metallic Lithium. Most simple organolithium reagents can be prepared by reaction of an appropriate halide with lithium metal. The method is applicable to alkyl, aryl, and alkenyl lithium reagents.

As with organomagnesium reagents, there is usually loss of stereochemical integrity at the site of reaction during the preparation of alkyllithium compounds.²⁵ Alkenyllithium reagents can usually be prepared with retention of configuration of the double bond.^{26,27}

For some halides, it is advantageous to use finely powdered lithium and a catalytic amount of an aromatic hydrocarbon, usually naphthalene or 4,4'-di-*t*-butylbiphenyl (DTBB).²⁸ These reaction conditions involve either radical anions or dianions generated by reduction of the aromatic ring (see Section 5.6.1.2), which then convert the halide to a radical anion. Several useful functionalized lithium reagents have been prepared by this method. In the third example below, the reagent is trapped in situ by reaction with benzaldehyde.

Ref. 30

Ref. 31

Alkylolithium reagents can also be generated by reduction of sulfides.³² Alkenyl-lithium and substituted alkylolithium reagents can be prepared from sulfides,³³ and sulfides can be converted to lithium reagents by the catalytic electron transfer process described for halides.³⁴

Ref. 35

This technique is especially useful for the preparation of α -lithio ethers, sulfides, and silanes.³⁶ The lithium radical anions of naphthalene, 4, 4'-di-*t*-butyldiphenyl (DTBB) or dimethylaminonaphthalene (LDMAN) are used as the reducing agent.

The simple alkylolithium reagents exist mainly as hexamers in hydrocarbon solvents.³⁷ In ethers, tetrameric structures are usually dominant.³⁸ The tetramers,

in turn, are solvated with ether molecules.³⁹ Phenyllithium is tetrameric in cyclohexane and a mixture of monomer and dimer in THF.⁴⁰ Chelating ligands such as tetramethylenediamine (TMEDA) reduce the degree of aggregation.⁴¹ Strong donor molecules such as hexamethylphosphorotriamide (HMPA) and *N,N*-dimethylpropyleneurea (DMPU) also lead to more dissociated and more reactive organolithium reagents.⁴² NMR studies on phenyllithium show that TMEDA, other polyamine ligands, HMPA, and DMPU favor monomeric solvated species.⁴³

The crystal structures of many organolithium compounds have been determined.⁴⁴ Phenyllithium has been crystallized as an ether solvate. The structure is tetrameric with lithium and carbon atoms at alternating corners of a highly distorted cube. The lithium atoms form a tetrahedron and the carbons are associated with the faces of the tetrahedron. Each carbon is 2.33 Å from the three neighboring lithium atoms and an ether molecule is coordinated to each lithium atom. Figures 7.2a and b show, respectively, the Li–C cluster and the complete array of atoms, except for hydrogen.⁴⁵ Section 6.2 of Part A provides additional information on the structure of organolithium compounds.

7.1.2.2. Preparation by Lithiation. There are three other general methods that are very useful for preparing organolithium reagents. The first of these is *hydrogen-metal exchange* or *metallation*, which for the specific case of lithium is known as *lithiation*. This reaction is the usual method for preparing alkynylmagnesium and alkynyllithium reagents. The reactions proceed readily because of the relative acidity of the hydrogen bound to *sp* carbon.

Although of limited utility for other types of Grignard reagents, metallation is an important means of preparing a variety of organolithium compounds. The position of lithiation is determined by the relative acidity of the available hydrogens and the directing effect of substituent groups. Benzylic and allylic hydrogens are relatively reactive toward lithiation because of the resonance stabilization of the resulting anions.⁴⁶ Substituents that can coordinate to the lithium atom, such as alkoxy, amido, sulfoxide, and sulfonyl, have a powerful influence on the position and rate of lithiation of aromatic compounds.⁴⁷ Some substituents, such as *t*-butoxycarbonylamido and carboxy, undergo deprotonation during the lithiation process.⁴⁸ The methoxymethoxy substituent is particularly useful among the alkoxy directing groups. It can provide selective lithiation and, being an acetal, is readily removed by hydrolysis.⁴⁹ In heteroaromatic compounds the preferred site for lithiation is usually adjacent to the heteroatom.

The features that characterize the activating groups include an electron pair that can coordinate lithium and polarity that can stabilize the anionic character.⁵⁰ Geometric factors are also important. For amido groups, for example, it has been deduced by comparison of various cyclic systems that the preferred geometry is for the activating amide group to be coplanar with the position of lithiation.⁵¹ If competing nucleophilic attack is a possibility, as in tertiary amides, steric bulk is also an important factor. Consistent with the importance of polar and electrostatic effects in lithiation, a fluoro substituent is a good directing substituent. Amide bases such as LDA and LTMP give better results than alkylolithium reagents. With these bases, fluorine was found to promote *ortho* lithiation selectively over such directing groups as methoxy and diethylaminocarbonyloxy.⁵²

Scheme 7.1 gives some examples of the preparation of organolithium compounds by lithiation. A variety of directing groups is represented, including methoxy (Entry 1), diethylaminocarbonyl (Entry 2), *N,N*-dimethylimidazolyl (Entry 3), *t*-butoxycarbonylamido (Entry 4), carboxy (Entry 5), and neopentoxycarbonyl (Entry 6). In the latter case, LDA is used as the base to avoid nucleophilic addition to the carbonyl group. The tri-*i*-propyl borate serves to trap the lithiation product as it is formed and prevent further reactions with the ester carbonyl. Entry 7 is a typical lithiation of a heteroaromatic molecule, and Entry 8 shows the lithiation of methyl vinyl ether. The latter reaction is dependent on the coordination and polar effect of the methoxy group and the relative acidity of the sp^2 C–H bond. Entry 9 is an allylic lithiation, promoted by the trimethylsiloxy group. Entry 10 is an interesting lithiation of an epoxide. The silyl substituent also has a modest stabilizing effect (see Part A, Section 3.4.2).

Reaction conditions can be modified to accelerate the rate of lithiation when necessary. Addition of tertiary amines, especially TMEDA, facilitates lithiation⁵³ by coordination at the lithium and promoting dissociation of aggregated structures. Kinetic and spectroscopic evidence indicates that in the presence of TMEDA lithiation of methoxybenzene involves the solvated dimeric species $(\text{BuLi})_2(\text{TMEDA})_2$.⁵⁴ The reaction shows an isotope effect for the *o*-hydrogen, establishing that proton abstraction is rate determining.⁵⁵ It is likely that there is a precomplexation between the methoxybenzene and organometallic dimer.

The lithiation process has been modeled by MP2/6-31 + G* calculations. The TSs for lithiation of fluorobenzene and methoxybenzene have lithium nearly in the aromatic plane and coordinated to the directing group as shown in Figure 7.3.⁵⁶ Although these structures represent lithiations as occurring through a monomeric species, similar effects are present in dimers or aggregates.^{50b} There is a considerable electrostatic component to the stabilization of the TS.^{50a} It has also been pointed out that the coordination of the Lewis acid Li^+ at the methoxy or fluorine group decreases the π -donor capacity of the groups and accentuates their σ -EWG capacity. The combination of these interactions is responsible for the activating effects of these groups.

Lithiation of alkyl groups is also possible and again a combination of donor chelation and polar stabilization of anionic character is required. Amides and carbamates can be lithiated α to the nitrogen.

Ref. 58

Studies with bicyclic carbamates of general structure **1** indicated that proximity and alignment of the carbonyl oxygen to the lithiation site is a major factor in determining the rate of lithiation.⁵⁹

Bicyclic structures of this type are more reactive than monocyclic or acyclic carbamates, indicating that a relatively rigid orientation of the carbonyl group is favorable to lithiation. Substituted formamidines can also be lithiated.⁶⁰

β -Lithiation has also been observed for deprotonated secondary amides of 3-phenylpropanoic acid.

Ref. 62

As with aromatic lithiation, the mechanism of directed lithiation in these systems appears to involve an association between the activating substituent and the lithiating agent.⁶³

Alkenyllithium compounds are intermediates in the *Shapiro reaction*, which is discussed in Section 5.7.2. The reaction can be run in such a way that the organolithium compound is generated in high yield and subsequently allowed to react with a variety of electrophiles.⁶⁴ This method provides a route to vinyl lithium compounds starting from a ketone.

Ref. 65

Hydrocarbons lacking directing substituents are not very reactive toward metalation, but it has been found that a mixture of *n*-butyllithium and potassium *t*-butoxide⁶⁶ is sufficiently reactive to give allyl anions from alkenes such as isobutene.⁶⁷

7.1.2.3. Preparation by Halogen-Metal Exchange. Halogen-metal exchange is another important method for preparation of organolithium reagents. The reaction proceeds in the direction of forming the more stable organolithium reagent, that is, the one derived from the more acidic organic compound. Thus, by use of the very basic organolithium compounds *n*-butyl- or *t*-butyllithium, halogen substituents at more acidic sp^2 carbons are readily exchanged to give the corresponding lithium compound. Halogen-metal exchange is particularly useful for converting aryl and alkenyl halides to the corresponding lithium compounds.

Ref. 68

Ref. 69

Halogen-metal exchange is a very fast reaction and is usually carried out at -60 to -120°C . This makes it possible to prepare aryllithium compounds containing functional groups, such as cyano and nitro, that react under the conditions required for preparation from lithium metal. Halogen-metal exchange is restricted for alkyl halides by competing reactions, but primary alkyllithium reagents can be prepared from iodides under carefully controlled conditions.⁷⁰

Retention of configuration is sometimes observed when organolithium compounds are prepared by halogen-metal exchange. The degree of retention is low for exchange of most alkyl systems,⁷¹ but it is normally high for cyclopropyl and vinyl halides.⁷² Once formed, both cyclopropyl and vinyl lithium reagents retain their configuration at room temperature.

Scheme 7.2 gives some examples of preparation of organolithium compounds by halogen-metal exchange. Entries 1, 2, and 3 are representative low-temperature preparations of alkenyllithium reagents. Entry 4 involves a cyclopropyl bromide. Both the *cis* and *trans* isomers react with retention of configuration. In Entries 1, 3, and 4, two equivalents of *t*-butyllithium are required because the *t*-butyl halide formed by exchange consumes one equivalent. Entry 5 is an example of retention of configuration at a double bond. Entries 6 and 7 show aryl bromides with functional groups that

are reactive toward organometallic compounds at higher temperature, but which can undergo the halogen-metal reaction successfully at low temperature. Entry 8 is an example of the use of lithium naphthalenide for halogen-metal exchange.

7.1.2.4. Preparation by Metal-Metal Exchange. A third useful method of preparing organolithium reagents involves *metal-metal exchange* or *transmetallation*. The reaction between two organometallic compounds proceeds in the direction of placing the more electropositive metal at the more acidic carbon position. Exchanges between organotin reagents and alkyl lithium reagents are particularly significant from a synthetic point of view. Terminal alkenyllithium compounds can be made from

vinylstannanes, which are available by addition of stannanes to terminal alkynes (see Section 9.3.1).

Ref. 73

Ref. 74

Ref. 75

The α -tri-*n*-butylstannyl derivatives needed for the latter two examples are readily available.

The exchange reactions of α -alkoxystannanes occur with retention of configuration at the carbon-metal bond.⁷⁶

7.2. Reactions of Organomagnesium and Organolithium Compounds

7.2.1. Reactions with Alkylating Agents

Organomagnesium and organolithium compounds are strongly basic and nucleophilic. Despite their potential to react as nucleophiles in $\text{S}_{\text{N}}2$ substitution reactions, this reaction is of limited utility in synthesis. One limitation on alkylation reactions is competition from electron transfer processes, which can lead to radical reactions. Methyl and other primary iodides usually give the best results in alkylation reactions.

HMPA can accelerate the reaction and improve yields when electron transfer is a complication.⁷⁷

Organolithium reagents in which the carbanion is delocalized are more useful than alkylolithium reagents in alkylation reactions. Allyllithium and benzylolithium reagents can be alkylated and with secondary alkyl bromides and a high degree of inversion of configuration is observed.⁷⁸

Alkenyllithium reagents can be alkylated in good yields by alkyl iodides and bromides.⁷⁹

The reactions of aryllithium reagents are accelerated by inclusion of potassium alkoxides.⁸⁰

Alkylation by allylic halides is usually a satisfactory reaction, and in this case the reaction may proceed through a cyclic mechanism.⁸¹ For example, when 1- ^{14}C -allyl chloride reacts with phenyllithium, about three-fourths of the product has the labeled carbon at the terminal methylene group.

Coupling of certain lithiated reagents with aryl and vinyl halides is also possible.⁸² These reactions probably proceed by a fast halogen-lithium exchange, generating the alkyl halide, which then undergoes substitution. This reaction has been applied to β -lithio benzamides.⁸³

Intramolecular reactions are useful for forming small rings. The reaction of 1,3-, 1,4-, and 1,5-diiodides with *t*-butyllithium is an effective means of ring closure, but 1,6-diiodides give very little cyclization.⁸⁴

Functionalized organolithium reagents can be prepared and alkylated. The configuration of the dioxanyl reagent **2** proved to be subject to control.⁸⁵ The kinetically favored *trans* lithio derivative is converted to the more stable *cis* isomer at 20° C. Both isomers were methylated with *retention* of configuration at saturated carbon.

Both trialkylsilyl and trialkylstannyl halides usually give high yields of substitution products with organolithium reagents, and this is an important route to silanes and stannanes (see Section 9.2.1 and 9.3.1).

Grignard reagents are somewhat less reactive toward alkylation but can be of synthetic value, especially when methyl, allyl, or benzyl halides are involved.

Synthetically useful alkylation of Grignard reagents can also be carried out with alkyl sulfonates and sulfates.

7.2.2. Reactions with Carbonyl Compounds

7.2.2.1. Reactions of Grignard Reagents. The most important reactions of Grignard reagents for synthesis involve addition to carbonyl groups. The TS for addition of Grignard reagents is often represented as a cyclic array containing the carbonyl group and two molecules of the Grignard reagent. There is considerable evidence favoring this mechanism involving a termolecular complex.⁸⁹

When the carbonyl carbon is substituted with a potential leaving group, the tetrahedral adduct can break down to regenerate a C=O bond and a second addition step can occur. Esters, for example are usually converted to tertiary alcohols, rather than ketones, in reactions with Grignard reagents.

Grignard reagents add to nitriles and, after hydrolysis of the reaction mixture, a ketone is obtained, with hydrocarbons being the preferred solvent for this reaction.⁹⁰

Ketones can also be prepared from acyl chlorides by reaction at low temperature using an excess of acyl chloride. Tetrahydrofuran is the preferred solvent.⁹¹ The reaction conditions must be carefully controlled to prevent formation of tertiary alcohol by addition of a Grignard reagent to the ketone as it is formed.

⁹¹. F. Sato, M. Inoue, K. Oguro, and M. Sato, *Tetrahedron Lett.*, 4303 (1979).

2-Pyridinethiolate esters, which are easily prepared from acyl chlorides, also react with Grignard reagents to give ketones (see Entry 6 in Scheme 7.3).⁹² *N*-Methoxy-*N*-methylamides are also converted to ketones by Grignard reagents (see Entries 17 and 18).

Aldehydes can be obtained by reaction of Grignard reagents with triethyl orthoformate. The addition step is preceded by elimination of one of the alkoxy groups to generate an electrophilic oxonium ion. The elimination is promoted by the magnesium ion acting as a Lewis acid.⁹³ The acetals formed by the addition are stable to the reaction conditions, but are hydrolyzed to aldehydes by aqueous acid.

Aldehydes can also be obtained from Grignard reagents by reaction with formamides, such as *N*-formylpiperidine. In this case, the initial adducts are stable and the aldehyde is not formed until hydrolysis during workup.

Ref. 94

The addition of Grignard reagents to aldehydes, ketones, and esters is the basis for the synthesis of a wide variety of alcohols, and several examples are given in Scheme 7.3. Primary alcohols can be made from formaldehyde (Entry 1) or, with addition of two carbons, from ethylene oxide (Entry 2). Secondary alcohols are obtained from aldehydes (Entries 3 to 6) or formate esters (Entry 7). Tertiary alcohols can be made from esters (Entries 8 and 9) or ketones (Entry 10). Lactones give diols (Entry 11). Aldehydes can be prepared from trialkyl orthoformate esters (Entries 12 and 13). Ketones can be made from nitriles (Entries 14 and 15), pyridine-2-thiol esters (Entry 16), *N*-methoxy-*N*-methyl carboxamides (Entries 17 and 18), or anhydrides (Entry 19). Carboxylic acids are available by reaction with CO₂ (Entries 20 to 22). Amines can be prepared from imines (Entry 23). Two-step procedures that involve formation and dehydration of alcohols provide routes to certain alkenes (Entries 24 and 25).

Several Grignard reactions are used on an industrial scale in drug synthesis.⁹⁵ The syntheses of both tamoxifen and droloxifene, which are estrogen antagonists used in treatment of breast cancer and osteoporosis, respectively, involve Grignard addition reactions.⁹⁶

Grignard reagents are quite restricted in the types of functional groups that can be present in either the organometallic or the carbonyl compound. Alkene, ether, and acetal functionality usually causes no difficulty but unprotected OH, NH, SH, or carbonyl groups cannot be present and CN and NO₂ groups cause problems in many cases.

Grignard additions are sensitive to steric effects and with hindered ketones a competing process leading to reduction of the carbonyl group can occur. A cyclic TS is involved.

⁹⁵ F. R. Busch and D. M. DeAntonis, in *Grignard Reagents: New Developments*, H. G. Richey, Jr., ed., Wiley, New York, 2000, pp. 175–181.

⁹⁶ R. McCaque, *J. Chem. Soc., Perkin Trans. I*, 1011 (1987); M. Schickaneder, R. Loser, and M. Grill, US Patent, 5,047,431 (1991).

The extent of this reaction increases with the steric bulk of the ketone and Grignard reagent. For example, no addition occurs between diisopropyl ketone and isopropylmagnesium bromide, and the reduction product diisopropylcarbinol is formed in 70% yield.⁹⁷ Competing reduction can be minimized in troublesome cases by using benzene or toluene as the solvent.⁹⁸ Alkyl lithium compounds are much less prone to reduction and are preferred for the synthesis of highly substituted alcohols. This is illustrated by the comparison of the reaction of ethyllithium and ethylmagnesium bromide with adamantone. A 97% yield of the tertiary alcohol is obtained with ethyllithium, whereas the Grignard reagent gives mainly the reduction product.⁹⁹

Enolization of the ketone is also sometimes a competing reaction. Since the enolate is unreactive toward nucleophilic addition, the ketone is recovered unchanged after hydrolysis. Enolization has been shown to be especially important when a considerable portion of the Grignard reagent is present as an alkoxide.¹⁰⁰ Alkoxides are formed as the addition reaction proceeds but can also be present as the result of oxidation of some of the Grignard reagent by oxygen during preparation or storage. As with reduction, enolization is most seriously competitive in cases where addition is retarded by steric factors.

Structural rearrangements are not encountered with saturated Grignard reagents, but allylic and homoallylic systems can give products resulting from isomerization. NMR studies indicate that allylmagnesium bromide exists as a σ -bonded structure in which there is rapid equilibration of the two terminal carbons.¹⁰¹ Similarly,

2-butenylmagnesium bromide and 1-methyl-2-propenylmagnesium bromide are in equilibrium in solution.

Addition products are often derived from the latter compound, although it is the minor component at equilibrium.¹⁰² Addition is believed to occur through a cyclic process that leads to an allylic shift.

3-Butenylmagnesium bromide is in equilibrium with a small amount of cyclopropylmethylmagnesium bromide. The existence of the mobile equilibrium has been established by deuterium-labeling techniques.¹⁰³ Cyclopropylmethylmagnesium bromide¹⁰⁴ (and cyclopropylmethylolithium¹⁰⁵) can be prepared by working at low temperature. At room temperature, the ring-opened 3-butenyl reagents are formed.

When the double bond is further removed, as in 5-hexenylmagnesium bromide, there is no evidence of a similar equilibrium.¹⁰⁶

The corresponding lithium reagent remains uncyclized at -78°C , but cyclizes on warming.¹⁰⁷ γ -, δ -, and ϵ -Alkynyl lithium reagents undergo *exo* cyclization to α -cycloalkylidene isomers.¹⁰⁸ Anion-stabilizing substituents are required for the strained three- and four-membered rings, but not for the *exo*-5 cyclization. The driving

force for cyclization is the formation of an additional C–C σ -bond and the formation of a more stable (sp^2 versus sp^3) carbanion.

An alternative to preparation of organometallic reagents followed by reaction with a carbonyl compound is to generate the organometallic intermediate in situ in the presence of the carbonyl compound. The organometallic compound then reacts immediately with the carbonyl compound. This procedure is referred to as the *Barbier reaction*.¹⁰⁹ This technique has no advantage over the conventional one for most cases for magnesium or lithium reagents. However, when the organometallic reagent is very unstable, it can be a useful method. Allylic halides, which can be difficult to convert to Grignard reagents in good yield, frequently give better results in the Barbier procedure. Since solid metals are used, one of the factors affecting the rate of the reaction is the physical state of the metal. Ultrasonic irradiation has been found to have a favorable effect on the Barbier reaction, presumably by accelerating the generation of reactive sites on the metal surface.¹¹⁰

7.2.2.2. Reactions of Organolithium Compounds. The reactivity of organolithium reagents toward carbonyl compounds is generally similar to that of Grignard reagents. The lithium reagents are less likely to undergo the competing reduction reaction with ketones, however.

Organolithium compounds can add to α, β -unsaturated ketones by either 1,2- or 1,4-addition. The most synthetically important version of the 1,4-addition involves organocopper intermediates, and is discussed in Chap 8. However, 1,4-addition is observed under some conditions even in the absence of copper catalysts. Highly reactive organolithium reagents usually react by 1,2-addition, but the addition of small amounts of HMPA has been found to favor 1,4-addition. This is attributed to solvation of the lithium ion, which attenuates its Lewis acid character toward the carbonyl oxygen.¹¹¹

One reaction that is quite efficient for lithium reagents but poor for Grignard reagents is the synthesis of ketones from carboxylic acids.¹¹² The success of the

¹¹². M. J. Jorgenson, *Org. React.*, **18**, 1 (1971).

reaction depends on the stability of the dilithio adduct that is formed. This intermediate does not break down until hydrolysis, at which point the ketone is liberated. Some examples of this reaction are shown in Section B of Scheme 7.4.

A study aimed at optimizing yields in this reaction found that carbinol formation was a major competing process if the reaction was not carried out in such a way that all of the lithium compound was consumed prior to hydrolysis.¹¹³ Any excess lithium reagent that is present reacts extremely rapidly with the ketone as it is formed by hydrolysis. Another way to avoid the problem of carbinol formation is to quench the reaction mixture with trimethylsilyl chloride.¹¹⁴ This procedure generates the disilyl acetal, which is stable until hydrolysis.

The synthesis of unsymmetrical ketones can be carried out in a tandem one-pot process by successive addition of two different alkyllithium reagents.¹¹⁵

N-Methyl-*N*-methoxyamides are also useful starting materials for preparation of ketones. Again, the reaction depends upon the stability of the tetrahedral intermediate against elimination and a second addition step. In this case chelation with the *N*-methoxy substituent is responsible.

Scheme 7.4 illustrates some of the important synthetic reactions in which organolithium reagents act as nucleophiles. The range of reactions includes $\text{S}_{\text{N}}2$ -type alkylation (Entries 1 to 3), epoxide ring opening (Entry 4), and formation of alcohols by additions to aldehydes and ketones (Entries 5 to 10). Note that in Entry 2, alkylation takes place mainly at the γ -carbon of the allylic system. The ratio favoring γ -alkylation

is higher for the *t*-butoxy ether than for ethers with smaller groups. There are several means of preparing ketones using organolithium reagents. Apart from addition to carboxylate salts (Entries 11 to 13), acylation with acyl chlorides (Entry 14), anhydrides (Entry 15), or *N*-methoxy-*N*-methylcarboxyamides (Entry 16) can be used. Carboxylic acids can be made by carbonation with CO₂ (Entries 17 and 18). Aldehydes can be prepared by reactions with DMF (Entry 19). Entry 20 is the alkylation of a stabilized allylic lithium reagent.

In addition to applications as nucleophiles, the lithium reagents have enormous importance in synthesis as bases and as lithiating reagents. The commercially available methyl, *n*-butyl, *s*-butyl, and *t*-butyl reagents are used frequently in this context.

7.2.2.3. Stereoselectivity of Addition to Ketones. The stereochemistry of the addition of both organomagnesium and organolithium compounds to cyclohexanones is similar.¹¹⁶ With unhindered ketones, the stereoselectivity is not high but there is generally a preference for attack from the equatorial direction to give the axial alcohol. This preference for the equatorial approach increases with the size of the alkyl group. With alkyllithium reagents, added salts improve the stereoselectivity. For example, one equivalent of LiClO₄, enhances the proportion of the axial alcohol in the addition of methyllithium to 4-*t*-butylcyclohexanone.¹¹⁷

Bicyclic ketones react with organometallic reagents to give the products of addition from the less hindered face of the carbonyl group.

The stereochemistry of addition of organometallic reagents to chiral carbonyl compounds parallels the behavior of the hydride reducing agents, as discussed in Section 5.3.2. Organometallic compounds were included in the early studies that established the preference for addition according to Cram's rule.¹¹⁸

¹¹⁶ E. C. Ashby and J. T. Laemmle, *Chem. Rev.*, **75**, 521 (1975).

¹¹⁷ E. C. Ashby and S. A. Noding, *J. Org. Chem.*, **44**, 4371 (1979).

¹¹⁸ D. J. Cram and F. A. A. Elhafez, *J. Am. Chem. Soc.*, **74**, 5828 (1952).

The interpretation of the basis for this stereoselectivity can be made in terms of the steric, torsional, and stereoelectronic effects discussed in connection with reduction by hydrides. It has been found that crown ethers enhance stereoselectivity in the reaction of both Grignard reagents and alkyllithium compounds.¹¹⁹ This effect was attributed to decreased electrophilicity of the metal cations in the presence of the crown ether. The attenuated reactivity leads to greater selectivity.

For ketones and aldehydes in which adjacent substituents permit the possibility of chelation with a metal ion, the stereochemistry can often be interpreted in terms of the steric requirements of the chelated TS. In the case of α -alkoxyketones, for example, an assumption that both the alkoxy and carbonyl oxygens are coordinated with the metal ion and that addition occurs from the less hindered face of this chelate correctly predicts the stereochemistry of addition. The predicted product dominates by as much as 100:1 for several Grignard reagents.¹²⁰ Further supporting the importance of chelation is the correlation between rate and stereoselectivity. Groups that facilitate chelation cause an increase in both rate and stereoselectivity.¹²¹ This indicates that chelation not only favors a specific TS geometry, but also lowers the reaction barrier by favoring metal ion complexation.

The addition of a Grignard reagent to an unsymmetrical ketone generates a new stereogenic center and is potentially enantioselective in the presence of an element of chirality. Perhaps because the reactions are ordinarily very fast, there are relatively few cases in which such reactions are highly enantioselective. The magnesium salt of TADDOL promotes enantioselective additions to acetophenone.¹²² These particular reactions occur under heterogeneous conditions and are quite slow at -100°C . Although the details of the mechanism are unclear, the ligand must establish a chiral environment that controls the facial selectivity of the additions.

In this section we discuss organometallic derivatives of zinc, cadmium, mercury, and indium. These Group IIB and IIIB metals have the d^{10} electronic configuration in the +2 and +3 oxidation states, respectively. Because of the filled d level, the +2 or +3 oxidation states are quite stable and reactions of these organometallics do not usually involve changes in oxidation level. This property makes the reactivity patterns of Group IIB and IIIB organometallics more similar to derivatives of Group IA and IIA metals than to transition metals having vacancies in the d levels. The IIB metals, however, are less electropositive than the IA and IIA metals and the nucleophilicity of the organometallics is less than for organolithium or organomagnesium compounds. Many of the synthetic applications of these organometallics are based on this attenuated reactivity and involve the use of a specific catalyst to promote reaction.

7.3.1. Organozinc Compounds

Organozinc reagents have become the most useful of the Group IIB organometallics in terms of synthesis.¹²³ Although they are much less reactive than organolithium or organomagnesium reagents, their addition to aldehydes can be catalyzed by various Lewis acids or by coordinating ligands. They have proven particularly adaptable to enantioselective additions. There are also important reactions of organozinc reagents that involve catalysis by transition metals, and these reactions are discussed in Chapter 8.

7.3.1.1. Preparation of Organozinc Compounds. Organozinc compounds can be prepared by reaction of Grignard or organolithium reagents with zinc salts. When Grignard reagents are treated with ZnCl_2 and dioxane, a dioxane complex of the magnesium halide precipitates, leaving a solution of the alkylzinc reagent. A one-pot process in which the organic halide, magnesium metal, and zinc chloride are sonicated is another method for their preparation.¹²⁴ Organozinc compounds can also be prepared from organic halides by reaction with highly reactive zinc metal.¹²⁵ Simple alkylzinc compounds, which are distillable liquids, can also be prepared from alkyl halides and a Zn-Cu couple.¹²⁶ Dimethyl-, diethyl-, di-*n*-propyl-, and diphenylzinc are commercially available.

Arylzinc reagents can be made from aryl halides with activated zinc¹²⁷ or from Grignard reagents by metal-metal exchange with zinc salts.¹²⁸

Allylic zinc reagents can be prepared in situ in aqueous solution in the presence of aldehydes.¹²⁹ These reactions show a strong preference for formation of the more branched product. This suggests that the reactions occur by coordination of the zinc reagent at the carbonyl oxygen and that addition proceeds by a cyclic mechanism, similar to that for allylic Grignard reagents. The kinetic isotope of the reaction measured under these conditions is consistent with a cyclic mechanism.¹³⁰

An attractive feature of organozinc reagents is that many functional groups that would interfere with organomagnesium or organolithium reagents can be present in organozinc reagents.^{131,132} Functionalized reagents can be prepared by halogen-metal exchange reactions with diethylzinc.¹³³ The reaction equilibrium is driven to completion by use of excess diethylzinc and removal of the ethyl iodide by distillation. The pure organozinc reagent can be obtained by removal of the excess diethylzinc under vacuum.

These reactions are subject to catalysis by certain transition metal ions and with small amounts of MnBr_2 or CuCl the reaction proceeds satisfactorily with alkyl bromides.¹³⁴

Another effective catalyst is $\text{Ni}(\text{acac})_2$.¹³⁵

Organozinc reagents can also be prepared from trialkylboranes by exchange with dimethylzinc.¹³⁶

This route can be used to prepare enantiomerically enriched organozinc reagents by asymmetric hydroboration (see Section 4.5.3), followed by exchange with diisopropylzinc. Trisubstituted cycloalkenes such as 2-methyl or 2-phenylcyclohexene give an enantiomeric purity greater than 95%. The exchange reaction takes place with retention of configuration.¹³⁷

Exchange with boranes can also be used to prepare alkenylzinc reagents.¹³⁸

Alkenylzinc reagents can also be made from alkynes by (Cp)₂TiCl₂-catalyzed hydrozincation (see Section 4.6).¹³⁹ The reaction proceeds with high *syn* stereoselectivity, and the regioselectivity corresponds to relative carbanion stability.

7.3.1.2. Reactions of Organozinc Compounds. Pure organozinc compounds are relatively unreactive toward addition to carbonyl groups, but the reactions are catalyzed by both Lewis acids and chelating ligands. When prepared in situ from ZnCl₂ and Grignard reagents, organozinc reagents add to carbonyl compounds to give carbinols.¹⁴⁰

This must reflect activation of the carbonyl group by magnesium ion, since ketones are less reactive to pure dialkylzinc reagents and tend to react by reduction rather than addition.¹⁴¹ The addition of alkylzinc reagents is also promoted by trimethylsilyl chloride, which leads to isolation of silyl ethers of the alcohol products.¹⁴²

High degrees of enantioselectivity have been obtained when alkylzinc reagents react with aldehydes in the presence of chiral ligands.¹⁴³ Among several compounds that have been used as ligands are *exo*-(dimethylamino)norborneol (**A**),¹⁴⁴ its morpholine analog (**B**),¹⁴⁵ diphenyl(1-methylpyrrolin-2-yl)methanol (**C**),¹⁴⁶ as well as ephedrine derivatives **D**¹⁴⁷ and **E**.¹⁴⁸

The enantioselectivity is the result of chelation of the chiral ligand to the zinc. The TS of the addition is believed to involve two zinc atoms. One zinc functions as a Lewis acid by coordination at the carbonyl oxygen and the other is the source of the nucleophilic carbon. The proposed TS for aminoalcohol **A**, for example, is shown below.¹⁴⁹

The catalytic cycle for these reactions is believed to involve dinuclear complexes formed among the zinc chelate, the aldehyde, and the zinc atom that releases the nucleophile.

The structures of the TSs have been explored computationally using combined B3LYP-MM methods.¹⁵⁰ There are four stereochemically distinct TSs, as shown in Figure 7.4. For the aminoalcohol ligands, the *anti-trans* arrangement is preferred. Steric factors destabilize the other TSs. The substituents on the ligand determine the facial selectivity of the aldehydes.

Fig. 7.4. Tricyclic transition structures for aminoalcohol catalysts: *syn* and *anti* refer to the relationship between the transferring group and the bidentate ligand; *cis* and *trans* refer to the relationship between the aldehyde substituent and the coordinating zinc. Reproduced from *J. Am. Chem. Soc.*, **125**, 5130 (2003), by permission of the American Chemical Society.

¹⁵⁰. T. Rasmussen and P.-O. Norrby, *J. Am. Chem. Soc.*, **125**, 5130 (2003).

Aryl zinc reagents are considerably more reactive than alkylzinc reagents in these catalyzed additions to aldehydes.¹⁵¹ Within the same computational framework, phenyl transfer is found to have about a 10 kcal/mol advantage over ethyl transfer.¹⁵² This is attributed to participation of the π orbital of the phenyl ring and to the greater electronegativity of the phenyl ring, which enhances the Lewis acid character of the catalytic zinc.

Aspects of the scale-up of aminoalcohol-catalyzed organozinc reactions with aldehydes have been investigated using *N,N*-diethylnorephedrine as a catalyst.¹⁵³ In addition to examples with aromatic aldehydes, 3-hexanol was prepared in 80% e.e.

Additions to aldehydes are also catalyzed by Lewis acids, especially $\text{Ti}(i\text{-OPr})_4$ and trimethylsilyl chloride.¹⁵⁴ Reactions of β -, γ -, δ -, and ϵ -iodozinc esters with benzaldehyde are catalyzed by $\text{Ti}(i\text{-OPr})_3\text{Cl}$.¹⁵⁵

Lewis acid-catalyzed additions can be carried out in the presence of other chiral ligands that induce enantioselectivity.¹⁵⁶ Titanium TADDOL induces enantioselectivity in alkylzinc additions to aldehydes. A variety of aromatic, alkyl, and α , β -unsaturated aldehydes give good results with primary alkylzinc reagents.¹⁵⁷

The *bis*-trifluoromethanesulfonamide of *trans*-cyclohexane-1,2-diamine also leads to enantioselective additions in 80% or greater e.e.¹⁵⁸

Ketones are less reactive than aldehydes toward organozinc reagents, and they are inherently less stereoselective because the differentiation is between two carbon substituents, rather than between a carbon substituent and hydrogen. Recently, a diol incorporating both *trans*-cyclohexanediamine and camphorsulfonic acid has proven effective in conjunction with titanium tetraisopropoxide.¹⁵⁹

The active catalyst is probably a dinuclear species in which the chiral ligand replaces isopropoxide.

Lewis acids catalyze the reaction of alkylzinc reagents with acyl chlorides.¹⁶⁰ The reaction is also catalyzed by transition metals, as is discussed in Chapter 8.

Immonium salts are sufficiently reactive to add organozinc halides in the absence of a catalyst.¹⁶¹ Diallyl amines were used because of the ease of subsequent deallylation (see Section 3.5.2).

The *Reformatsky reaction* is a classical reaction in which metallic zinc, an α -haloester, and a carbonyl compound react to give a β -hydroxyester.¹⁶² The zinc and α -haloester react to form an organozinc reagent. Because the carboxylate group can stabilize the carbanionic center, the product is essentially the zinc enolate of the dehalogenated ester.¹⁶³ The enolate effects nucleophilic attack on the carbonyl group.

With 2-alkylcyclohexanones, the reaction shows a modest preference for equatorial attack.¹⁶⁴

Fig. 7.5. Crystal structure of Reformatsky reagent of *t*-butyl bromoacetate crystallized from THF. Reproduced from *J. Chem. Soc., Chem. Commun.*, 553 (1983), by permission of the Royal Society of Chemistry.

The Reformatsky reaction is related to both organometallic and aldol addition reactions and probably involves a cyclic TS. The Reformatsky reagent from *t*-butyl bromoacetate crystallizes as a dimer having both O–Zn (enolate-like) and C–Zn (organometallic-like) bonds (see Figure 7.5).¹⁶⁵

It is believed that the reaction occurs through the monomer.¹⁶⁶ Semiempirical MO (PM3) calculations suggest a boat TS.¹⁶⁷ There do not seem to be any definitive experimental studies that define the mechanism precisely.

Several techniques have been used to “activate” the zinc metal and improve yields. For example, pretreatment of zinc dust with a solution of copper acetate gives a more reactive zinc-copper couple.¹⁶⁸ Exposure to trimethylsilyl chloride also activates the zinc.¹⁶⁹ Wilkinson’s catalyst, $\text{RhCl}(\text{PPh}_3)_3$ catalyzes formation of Reformatsky reagents from diethylzinc, and reaction occurs under very mild conditions.¹⁷⁰

¹⁷⁰ K. Kanai, H. Wakabayashi, and T. Honda, *Org. Lett.*, **2**, 2549 (2000).

These conditions also provide good yields in intramolecular reactions. There is a preference for formation of the *cis* product for five- and six-membered rings.

Scheme 7.5 gives some examples of the Reformatsky reaction. Zinc enolates prepared from α -haloketones can be used as nucleophiles in mixed aldol condensations (see Section 2.1.3). Entry 7 is an example. This type of reaction can be conducted in the presence of the Lewis acid diethylaluminum chloride, in which case addition occurs at -20°C .¹⁷¹

7.3.1.3. Related Reactions Involving Organozinc Compounds. Organozinc reagents can be converted to anionic “zincate” species by reaction with organolithium compounds.¹⁷² These reagents react directly with aldehydes and ketones to give addition products.¹⁷³

The 1:1 zincate reagent is believed to be dimeric. At higher ratios of organolithium compounds, 2:1 and 3:1 species can be formed.¹⁷⁴

Zincate reagents can add to imines with or without Lewis acid catalysis. Alkylimines require BF_3 but imines of pyridine-2-carboxaldehyde react directly. If the imines are derived from chiral amines, diastereoselectivity is observed. Both α -phenylethyl amine and ethyl valinate have been tried. Higher enantioselectivity was observed with mixed magnesium reagents.¹⁷⁵

Organozinc reagents have been used in conjunction with α -bromovinylboranes in a tandem route to *Z*-trisubstituted allylic alcohols. After preparation of the vinylborane, reaction with diethylzinc effects migration of a boron substituent with inversion of configuration and exchange of zinc for boron.¹⁷⁶ Addition of an aldehyde then gives the allylic alcohol. The reaction is applicable to formaldehyde; alkyl and aryl aldehydes; and to methyl, primary, and secondary boranes.

¹⁷⁶ Y. K. Chen and P. J. Walsh, *J. Am. Chem. Soc.*, **126**, 3702 (2004).

The reagent combination $\text{Zn}-\text{CH}_2\text{Br}_2-\text{TiCl}_4$ gives rise to an organometallic reagent known as *Lombardo's reagent*, which converts ketones to methylene groups.¹⁷⁷ The active reagent is presumed to be a dimetallated species that adds to the ketone under the influence of the Lewis acidity of titanium. β -Elimination then generates the methylene group.

Use of esters and 1,1-dibromoalkanes as reactants gives enol ethers.¹⁷⁸

A similar procedure starting with trimethylsilyl esters generates trimethylsilyl enol ethers.¹⁷⁹

Organozinc reagents are also used extensively in conjunction with palladium in a number of carbon-carbon bond-forming processes that are discussed in Section 8.2.

7.3.2. Organocadmium Compounds

Organocadmium compounds can be prepared from Grignard reagents or organolithium compounds by reaction with $\text{Cd}(\text{II})$ salts.¹⁸⁰ They can also be prepared directly from alkyl, benzyl, and aryl halides by reaction with highly reactive cadmium metal generated by reduction of $\text{Cd}(\text{II})$ salts.¹⁸¹

The reactivity of these reagents is similar to the corresponding organozinc compounds.

The most common application of organocadmium compounds has been in the preparation of ketones by reaction with acyl chlorides. A major disadvantage of the use of organocadmium reagents is the toxicity and environmental problems associated with use of cadmium, and this has limited the recent use of organocadmium reagents.

Ref. 182

Ref. 183

7.3.3. Organomercury Compounds

There are several useful methods for preparation of organomercury compounds. The general metal-metal exchange reaction between mercury(II) salts and organolithium or magnesium compounds is applicable. The oxymercuration reaction discussed in Section 4.1.3 provides a means of acquiring certain functionalized organomercury reagents. Organomercury compounds can also be obtained by reaction of mercuric salts with trialkylboranes, although only primary alkyl groups react readily.¹⁸⁴ Other organoboron compounds, such as boronic acids and boronate esters also react with mercuric salts.

Alkenylmercury compounds can be prepared by hydroboration of an alkyne with catecholborane, followed by reaction with mercuric acetate.¹⁸⁵

¹⁸⁵ R. C. Larock, S. K. Gupta, and H. C. Brown, *J. Am. Chem. Soc.*, **94**, 4371 (1972).

The organomercury compounds can be used in situ or isolated as organomercuric halides.

Organomercury compounds are weak nucleophiles and react only with very reactive electrophiles. They readily undergo electrophilic substitution by halogens.

Ref. 184

Ref. 186

Organomercury reagents do not react with ketones or aldehydes but Lewis acids cause reaction with acyl chlorides.¹⁸⁷ With alkenyl mercury compounds, the reaction probably proceeds by electrophilic attack on the double bond with the regiochemistry being directed by the stabilization of the β -carbocation by the mercury.¹⁸⁸

Most of the synthetic applications of organomercury compounds are in transition metal-catalyzed processes in which the organic substituent is transferred from mercury to the transition metal in the course of the reaction. Examples of this type of reaction are considered in Chapter 8.

7.3.4. Organoindium Reagents

Indium is a Group IIIB metal and is a congener of aluminum. Considerable interest has developed recently in the synthetic application of organoindium reagents.¹⁸⁹ One of the properties that makes indium useful is that its first oxidation potential is less than that of zinc and even less than that of magnesium, making it quite reactive as an electron donor to halides. Indium metal reacts with allylic halides in the presence of aldehydes to give the corresponding carbinols.

It is believed that the reaction proceeds through a cyclic TS and that the reagent is an In(I) species.¹⁹¹

A striking feature of the reactions of indium and allylic halides is that they can be carried out in aqueous solution.¹⁹² The aldehyde traps the organometallic intermediate as it is formed.

The reaction has been found to be applicable to functionalized allylic halides and aldehydes.

Ref. 194

7.4. Organolanthanide Reagents

The lanthanides are congeners of the Group IIIA metals scandium and yttrium, with the +3 oxidation state usually being the most stable. These ions are strong oxyphilic Lewis acids and catalyze carbonyl addition reactions by a number of nucleophiles. Recent years have seen the development of synthetic procedures involving lanthanide metals, especially cerium.¹⁹⁵ In the synthetic context, organocerium

compounds are usually prepared by reaction of organolithium compounds with CeCl_3 .¹⁹⁶ The precise details of preparation of the CeCl_3 and its reaction with the organolithium compound can be important to the success of individual reactions.¹⁹⁷ The organocerium compounds are useful for addition to carbonyl compounds that are prone to enolization or are sterically hindered.¹⁹⁸ The organocerium reagents retain strong nucleophilicity but show a much reduced tendency to effect deprotonation. For example, in addition of trimethylsilylmethyl lithium to relatively acidic ketones such as 2-indanone, the yield was greatly increased by use of the organocerium intermediate.¹⁹⁹

Organocerium reagents have been found to improve yields in additions to bicyclo[3.3.1]nonan-3-ones.²⁰⁰

An organocerium reagent gave better yields than either the lithium or Grignard reagents in addition to carbonyl at the 17-position on steroids.²⁰¹ Additions of both Grignard and organolithium reagents can be catalyzed by 5–10 mol % of CeCl_3 .

Cerium reagents have also been found to give improved yields in the reaction of organolithium reagents with carboxylate salts to give ketones.

Ref. 202

Amides, especially of piperidine and morpholine, give good yields of ketones on reaction with organocerium reagents.²⁰³ It has been suggested that the morpholine oxygen may interact with the oxyphilic cerium to stabilize the addition intermediate.

This procedure has been used with good results to prepare certain long-chain ketones that are precursors of pheromones.²⁰⁴

Organocerium reagents also show excellent reactivity toward nitriles and imines,²⁰⁵ and organocerium compounds were found to be the preferred organometallic reagent for addition to hydrazones in an enantioselective synthesis of amines.²⁰⁶

Reactions Involving Transition Metals

Introduction

In this chapter we discuss important synthetic reactions that involve transition metal compounds and intermediates. Reactions involving copper and palladium, the transition metals that have the widest applications in synthesis, are discussed in the first two sections. In the third section, we consider several other transition metals, including nickel, rhodium, and cobalt. In contrast to lithium, magnesium, and zinc, where the organometallic reagents are used in stoichiometric quantities, many of the transition metal reactions are catalytic processes. The mechanisms are described in terms of *catalytic cycles* that show the role of the catalytic species in the reaction and its regeneration. Another distinguishing feature of transition metal reactions is that they frequently involve changes in oxidation state at the metal atom. In the final two sections we deal with transition metal-catalyzed alkene exchange (*metathesis*) reactions and organometallic compounds that feature π bonding of the organic component.

8.1. Organocopper Intermediates

8.1.1. Preparation and Structure of Organocopper Reagents

The synthetic application of organocopper compounds received a major impetus from the study of the catalytic effect of copper salts on reactions of Grignard reagents with α,β -unsaturated ketones.¹ Although Grignard reagents normally add to such compounds to give the 1,2-addition product, the presence of catalytic amounts of Cu(I) results in conjugate addition. Mechanistic study pointed to a very fast reaction by an organocopper intermediate.

¹ H. O. House, W. L. Respess, and G. M. Whitesides, *J. Org. Chem.*, **31**, 3128 (1966).

Subsequently, much of the development of organocopper chemistry focused on stoichiometric reagents prepared from organolithium compounds. Several types of organometallic compounds can result from reactions of organolithium reagents with copper(I) salts.² Metal-metal exchange reactions using a 1:1 ratio of lithium reagent and a copper(I) salt give alkylcopper compounds that tend to be polymeric and are less useful in synthesis than the 2:1 or 3:1 “ate” compounds.

The 2:1 species are known as *cuprates* and are the most common synthetic reagents. Disubstituted Cu(I) species have the $3d^{10}$ electronic configuration and would be expected to have linear geometry. The Cu is a center of high electron density and nucleophilicity, and in solution, lithium dimethylcuprate exists as a dimer $[\text{LiCu}(\text{CH}_3)_2]_2$.³ The compound is often represented as four methyl groups attached to a tetrahedral cluster of lithium and copper atoms. However, in the presence of LiI, the compound seems to be a monomer of composition $(\text{CH}_3)_2\text{CuLi}$.⁴

Discrete diarylcuprate anions have been observed in crystals in which the lithium cation is complexed by crown ethers.⁵ Both tetrahedral Ph_4Cu_4 and linear $[\text{Ph}_2\text{Cu}]^-$ units have been observed in complex cuprates containing $(\text{CH}_3)_2\text{S}$ as a ligand. $[(\text{Ph})_3\text{Cu}]^{2-}$ units have also been observed as parts of larger aggregates.⁶ Larger clusters of composition $[(\text{Ph}_6\text{Cu}_4)\text{Li}]^-$ and $[\text{Ph}_6\text{Cu}_4\text{Mg}\cdot\text{OEt}_2]$ have been characterized by crystallography,⁷ as shown in Figure 8.1.

Cuprates with two different copper ligands have been developed. These compounds have important advantages in cases in which one of the substituents

is derived from a valuable synthetic intermediate. The group R, representing alkyl, alkenyl, or aryl, is normally transferred in preference to the other copper ligand. Table 8.1 presents some of these mixed cuprate reagents and summarizes their reactivity. The group listed first is the nonreactive copper ligand and R is the organic group that is delivered as a nucleophile.

There has been a great deal of study concerning the effect of solvents and other reaction conditions on the stability and reactivity of organocuprate species.⁸ These studies have found, for example, that $(\text{CH}_3)_2\text{S}\cdot\text{CuBr}$, a readily prepared and purified complex of CuBr, is an especially reliable source of Cu(I) for cuprate preparation.⁹ Copper(I) cyanide and iodide are also generally effective and, in some cases, preferable.¹⁰

An important type of mixed cuprate is prepared from a 2:1 ratio of an alkyllithium and CuCN.¹¹ Called *higher-order cyanocuprates*, their composition is $\text{R}_2\text{CuCNLi}_2$ in THF solution, but it is thought that most of the molecules are probably present as dimers. The cyanide does not seem to be bound directly to the copper, but rather to the lithium cations.¹² The dimers most likely adopt an eight-membered ring motif.¹³

These reagents are qualitatively similar in reactivity to other cuprates but they are more stable than the dialkylcuprates. As cyanocuprate reagents usually transfer only one of the two organic groups, it is useful to incorporate a group that does not transfer, and the 2-thienyl group has been used for this purpose.¹⁴ Usually, these reagents are prepared from an organolithium reagent, 2-thienyllithium, and CuCN. These reagents can also be prepared by reaction of an alkyl halide with 2-thienylcopper. The latter method is compatible with functionalized alkyl groups.¹⁵

In a mixed alkyl-thienyl cyanocuprate, only the alkyl substituent is normally transferred as a nucleophile.

Another type of mixed cyanocuprate has both methyl and alkenyl groups attached to copper. Interestingly, these reagents selectively transfer the alkenyl group in conjugate addition reactions.¹⁶ These reagents can be prepared from alkynes via hydrozirconation, followed by metal-metal exchange.¹⁷

Alkenylcyanocuprates can also be made by metal-metal exchange from alkenylstannanes.¹⁸

The 1:1 organocopper reagents can be prepared directly from the halide and highly reactive copper metal prepared by reducing Cu(I) salts with lithium naphthalenide.¹⁹ This method of preparation is advantageous for organocuprates containing substituents that are incompatible with organolithium compounds. For example, nitrophenyl and cyanophenyl copper reagents can be prepared in this way, as can alkylcopper reagents having ester and cyano substituents.²⁰ Allylic chlorides and acetates can also be converted to cyanocuprates by reaction with lithium naphthalenide in the presence of CuCN and LiCl.²¹

Organocopper reagents can also be prepared from Grignard reagents, which are generated and used in situ by adding a Cu(I) salt, typically the bromide, iodide, or cyanide.

8.1.2. Reactions Involving Organocopper Reagents and Intermediates

The most characteristic feature of the organocuprate reagents is that they are excellent *soft nucleophiles*, showing greater reactivity in S_N2 , S_N2' , and conjugate addition reactions than toward direct addition at carbonyl groups. The most important reactions of organocuprate reagents are nucleophilic displacements on halides and sulfonates, epoxide ring opening, conjugate additions to α,β -unsaturated carbonyl compounds, and additions to alkynes.²² These reactions are discussed in more detail in the following sections.

8.1.2.1. S_N2 and S_N2' Reactions with Halides and Sulfonates. Corey and Posner discovered that lithium dimethylcuprate can replace iodine or bromine by methyl in a wide variety of compounds, including aryl, alkenyl, and alkyl derivatives. This halogen displacement reaction is more general and gives higher yields than displacements with Grignard or lithium reagents.²³

Secondary bromides and tosylates react with inversion of stereochemistry, as in the classical S_N2 substitution reaction.²⁴ Alkyl iodides, however, lead to racemized product. Aryl and alkenyl halides are reactive, even though the direct displacement mechanism is not feasible. For these halides, the overall mechanism probably consists of two steps: an *oxidative addition* to the metal, after which the oxidation state of the copper is +3, followed by combination of two of the groups from the copper. This process, which is very common for transition metal intermediates, is called *reductive elimination*. The $[R'_2Cu]^-$ species is linear and the oxidative addition takes place perpendicular to this moiety, generating a T-shaped structure. The reductive elimination occurs between adjacent R and R' groups, accounting for the absence of R'–R' coupling product.

Allylic halides usually give both S_N2 and S_N2' products, although the mixed organocopper reagent $RCu-BF_3$ is reported to give mainly the S_N2' product.²⁵ Other leaving groups can also be used, including acetate and phosphate esters. Allylic acetates undergo displacement with an allylic shift (S_N2' mechanism).²⁶ The allylic substitution process may involve initial coordination with the double bond.²⁷

For substituted allylic systems, both α - and γ -substitution can occur. Reaction conditions can influence the α - versus γ -selectivity. For example, the reaction of geranyl acetate with several butylcopper reagents was explored. Essentially complete α - or γ -selectivity could be achieved by modification of conditions.²⁸ In either both CuCN and CuI led to preferential γ -substitution, whereas α -substitution was favored for all anions in THF.

3-Acetoxy-2-methyl-1-alkenes react primarily at C(1), owing to steric factors.²⁹

5-Acetoxy-1,3-alkadienes give mainly ϵ -alkylation with dialkylcopper-magnesium reagents.³⁰

High γ -selectivity has been observed for allylic diphenyl phosphate esters.^{26a}

The reaction of cyclic allylic acetates shows a preference for *anti* stereochemistry.³¹

The preferred stereoelectronic arrangement is perpendicular alignment of the acetate with respect to the double bond. For example, the *cis* and *trans* isomers of 1-vinyl-2-methylcyclohexyl acetate show divergent stereochemical results. Only the exocyclic *E*-isomer is formed from the *cis* compound, whereas the *trans* compound gives a 1:1 mixture of the *E*- and *Z*-isomers. This is the result of a strongly preferred conformation for the *cis* isomer, as opposed to a mixture of conformations for the *trans* isomer.³²

Excellent diastereoselectivity is observed for δ -oxy allylic acetates. The stereo-selectivity is attributed to a Felkin-type TS with addition *anti* to the oxy substituent.

Similar results were obtained using *n*-BuMgBr-CuCN and tertiary allylic acetates, although under these conditions there is competition from S_N2' substitution with primary acetates.³³ The stereoselectivity is reversed with a hydroxy group, indicating a switch to a chelated TS.

Propargylic acetates, halides, and sulfonates usually react with a double-bond shift to give allenes.³⁴ Some direct substitution product can be formed as well. A high ratio of allenic product is usually found with CH₃Cu-LiBr-MgBrI, which is prepared by addition of methylmagnesium bromide to a 1:1 LiBr-CuI mixture.³⁵

Halogens α to carbonyl groups can be successfully coupled using organocopper reagents. For example, 3,9-dibromocamphor is selectively arylated α to the carbonyl.

Ref. 36

Scheme 8.1 gives several examples of the use of coupling reactions of organocuprate reagents with halides and acetates. Entries 1 to 3 are examples of the

use of dialkylcuprates. In each case the halide is not susceptible to S_N2 substitution, but the oxidative addition mechanism is feasible. Entry 4 is an example of S_N2' substitution. This reaction, carried out simultaneously at two allylic chloride moieties, was used in the synthesis of the “juvenile hormone” of the moth *Cecropia*. Entry

5 illustrates the alkylation of a vinyl halide with retention of configuration at each stage of the reaction. Entry 6 is an example of a functionalized mixed magnesium-cyanocuprate reagent, which was prepared from an organozinc reagent by treatment with $(\text{CH}_3)_2\text{CuCNMg}_2\text{Cl}_2$. Entry 7 is an $\text{S}_{\text{N}}2'$ displacement on a tosylate that occurs stereospecifically. Entries 8 and 9 are $\text{S}_{\text{N}}2'$ displacements of allyl acetates.

8.1.2.2. Opening of Epoxides. Organocopper reagents are excellent nucleophiles for opening epoxide rings. Saturated epoxides are opened in good yield by lithium dimethylcuprate.³⁷ The methyl group is introduced at the less hindered carbon of the epoxide ring.

Even mixed reagents with Lewis acids attack at the less-substituted position, indicating dominance of the nucleophilic bond making over the electrophilic component of ring opening.³⁸

The predictable regio- and stereochemistry make these reactions valuable in establishing stereochemistry in both acyclic and cyclic systems.

With cyclohexene epoxides, the ring opening is *trans*-diaxial.

Epoxides with alkenyl substituents undergo alkylation at the double bond with a double-bond shift accompanying ring opening, leading to formation of allylic alcohols.

Ref. 42

8.1.2.3. Conjugate Addition Reactions. All of the types of mixed cuprate reagents described in Scheme 8.1 react by conjugate addition with enones. A number of improvements in methodology for carrying out the conjugate addition reactions have been introduced. The addition is accelerated by trimethylsilyl chloride alone or in combination with HMPA.⁴³ Under these conditions the initial product is a silyl enol ether. The mechanism of the catalysis remains uncertain, but it appears that the silylating reagent intercepts an intermediate and promotes carbon-carbon bond formation, as well as trapping the product by O-silylation.⁴⁴

This technique also greatly improves yields of conjugate addition of cuprates to α,β -unsaturated esters and amides.⁴⁵ Trimethylsilyl cyanide also accelerates conjugate addition.⁴⁶ Another useful reagent is prepared from a 1:1:1 ratio of organolithium reagent, CuCN, and $\text{BF}_3\text{-O}(\text{C}_2\text{H}_5)_2$.⁴⁷ The BF_3 appears to interact with the cyanocuprate reagent, giving a more reactive species.⁴⁸ The efficiency of the conjugate addition reaction is also improved by the inclusion of trialkylphosphines.⁴⁹ Even organocopper reagents prepared from a 1:1 ratio of organolithium compounds are reactive in the presence of phosphines.⁵⁰

The mechanism of conjugate addition reactions probably involves an initial complex between the cuprate and enone.⁵¹ The key intermediate for formation of the new carbon-carbon bond is an adduct formed between the enone and the organocopper reagent. The adduct is formulated as a Cu(III) species, which then undergoes reductive elimination. The lithium ion also plays a key role, presumably by Lewis acid coordination at the carbonyl oxygen.⁵² Solvent molecules also affect the reactivity of the complex.⁵³ The mechanism can be outlined as occurring in three steps.

Isotope effects indicate that the collapse of the adduct by reductive elimination is the rate-determining step.⁵⁴ Theoretical treatments of the mechanism suggest similar intermediates. (See Section 8.1.2.7 for further discussion of the computational results.)⁵⁵

There is a correlation between the reduction potential of the carbonyl compounds and the ease of reaction with cuprate reagents.⁵⁶ The more easily it is reduced, the more reactive the compound toward cuprate reagents. Compounds such as α , β -unsaturated esters and nitriles, which are not as easily reduced as the corresponding ketones, do not react as readily with dialkylcuprates, even though they are good acceptors in classical Michael reactions with carbanions. α , β -Unsaturated esters are marginal in terms of reactivity toward standard dialkylcuprate reagents, and β -substitution retards reactivity. The RCu-BF_3 reagent combination is more reactive toward conjugated esters and nitriles,⁵⁷ and additions to hindered α , β -unsaturated ketones are accelerated by BF_3 .⁵⁸

There have been many applications of conjugate additions in synthesis. Some representative reactions are shown in Scheme 8.2. Entries 1 and 2 are examples of addition of lithium dimethylcuprate to cyclic enones. The stereoselectivity exhibited in Entry 2 is the result of both steric and stereoelectronic effects that favor the approach *syn* to the methyl substituent. In particular, the axial hydrogen at C(6) hinders the α approach.

In Entry 3, the *trans* stereochemistry arises at the stage of the protonation of the enolate. Entry 4 gives rise to a *cis* ring juncture, as does the corresponding carbocyclic compound.⁵⁹ Models suggest that this is the result of a steric differentiation arising from the axial hydrogens on the α -face of the molecule.

Entries 5 to 9 illustrate some of the modified reagents and catalytic procedures. Entry 5 uses a phosphine-stabilized reagent, whereas Entry 6 includes BF_3 . Entry 7 involves use of TMS-Cl . Entries 8 and 9 involve cyanocuprates. In Entry 9, the furan ring is closed by a Mukaiyama-aldol reaction subsequent to the conjugate addition (Section 2.1.4).

⁵⁹ S. M. McElvain and D. C. Remy, *J. Am. Chem. Soc.*, **82**, 3960 (1960).

Entries 10 to 12 illustrate the use of organocopper conjugate addition in the synthesis of relatively complex molecules. The installation of a *t*-butyl group adjacent to a quaternary carbon in Entry 10 requires somewhat forcing conditions, but proceeds in good yield. In Entry 11, the addition is to a vinylogous ester, illustrating the ability of the BF_3 -modified reagents to react with less electrophilic systems. Steric shielding by the axial methoxymethyl substituent accounts for the stereoselectivity observed in Entry 12.

Prior to protonolysis, the products of conjugate addition are enolates and, therefore, potential nucleophiles. A useful extension of the conjugate addition method is to combine it with an alkylation step that adds a substituent at the α -position.⁶⁰ Several examples of this *tandem conjugate addition-alkylation* method are given in Scheme 8.3. In Entry 1 the characteristic β -attack on the *cis* decalone ring is observed (see Scheme 8.2, Entry 2). The alkylation gives a $\beta : \alpha$ ratio of 60:40. In Entry 2, the methylation occurs *anti* to the 4-substituent, presumably because of steric factors. These reactions are part of the synthesis of the cholesterol-lowering drug compactin. Entry 3 illustrates a pattern that has been extensively developed for the synthesis of prostaglandins. In this case, the dioxolane ring controls the stereoselectivity of the conjugate addition step and steric factors lead to *anti* alkylation and formation the *trans* product. Entry 4 is a part of a steroid synthesis. This reaction shows a 4:1 preference for methylation from the β -face (*syn* to the substituent). In Entry 5, the conjugate addition is followed by a Robinson annulation. The product provides a C,D-ring segment of the steroid skeleton.

8.1.2.4. Copper-Catalyzed Reactions. The cuprate reagents that were discussed in the preceding sections are normally prepared by reaction of an organolithium reagent with a copper(I) salt, using a 2:1 ratio of lithium reagent to copper(I). There are also valuable synthetic procedures that involve organocopper intermediates that are generated in the reaction system by use of only a catalytic amount of a copper salt.⁶¹ Coupling of Grignard reagents and primary halides and tosylates can be catalyzed by Li_2CuCl_4 .⁶² This method was used, for example, to synthesize long-chain carboxylic acids in more than 90% yield.⁶³

⁶⁰. For a review of such reactions, see R. J. K. Taylor, *Synthesis*, 364 (1985).

⁶¹. For a review, see E. Erdik, *Tetrahedron*, **40**, 641 (1984).

Another excellent catalyst for coupling is a mixture of $\text{CuBr} \cdot \text{S}(\text{CH}_3)_2$, LiBr , and LiSPh . This catalyst can effect coupling of a wide variety of Grignard reagents with tosylates and mesylates and is superior to Li_2CuCl_4 in coupling with secondary sulfonates.⁶⁴

These reactions presumably involve fast metal-metal exchange (see Section 7.1.2.4) generating a more nucleophilic organocopper intermediate. The reductive elimination regenerates an active Cu(I) species.

Other examples of catalytic substitutions can be found in Section A of Scheme 8.4.

Conjugate addition to α, β -unsaturated esters can often be effected by copper-catalyzed reaction with a Grignard reagent. Other reactions, such as epoxide ring opening, can also be carried out under catalytic conditions. Some examples of catalyzed additions and alkylations are given in Scheme 8.4. These reactions are similar to those carried out with the stoichiometric reagents and presumably involve catalytic cycles that regenerate the active organocopper species. A remarkable aspect of these reactions is that the organocopper cycle must be fast compared to normal organomagnesium reactions, since in many cases there is a potential for competing reactions. The alkylations include several substitutions on allylic systems (Entries 2, 3, and 7). Entry 8 shows that the catalytic process is also applicable to epoxide ring opening. The latter example is a case in which an allylic chloride is displaced in preference to an acetate. The conditions have been observed in related systems to be highly regio- ($\text{S}_{\text{N}}2'$) and stereo- (*anti*) specific.⁶⁵ The conjugate additions in Entries 9 to 12 show

⁶⁵ J.-E. Backvall, *Bull. Soc. Chim. Fr.*, 665 (1987).

that esters and enones (Entry 13) are reactive to the catalytic processes involving Grignard reagents. Entries 14 and 15 illustrate ketone syntheses from acyl chlorides and nitriles, respectively.

8.1.2.5. Mixed Organocopper-Zinc Reagents. The preparation of organozinc reagents is discussed in Section 7.3.1. Many of these reagents can be converted to mixed copper-zinc organometallics that have useful synthetic applications.⁶⁶ A virtue of these reagents is that they can contain a number of functional groups that are not compatible with the organolithium route to cuprate reagents. The mixed copper-zinc reagents are not very basic and can be prepared and allowed to react in the presence of weakly acidic functional groups that would protonate more basic organometallic reagents; for example, reagents containing secondary amide or indole groups can be prepared.⁶⁷ They are good nucleophiles, are especially useful in conjugate addition. Mixed zinc reagents can also be prepared by addition of CuCN to organozinc iodides.⁶⁸ They are analogous to the cyanocuprates prepared from alkyllithium and CuCN, but with Zn^{2+} in place of Li^+ , and react with enones, nitroalkenes, and allylic halides.⁶⁹

In addition to the use of stoichiometric amounts of cuprate or cyanocuprate reagents for conjugate addition, there are also procedures that require only a catalytic amount of copper and use organozinc reagents as the stoichiometric reagent.⁷⁰ Simple organozinc reagents, such as diethylzinc, undergo conjugate addition with 0.5 mol % CuO_3SCF_3 in the presence of a phosphine or phosphite.

Ref. 71

In the presence of LiI, TMS-Cl, and a catalytic amount of $(\text{CH}_3)_2\text{CuCNLi}_2$, conjugate addition of functionalized organozinc reagents occurs in good yield.

Ref. 72

Either CuI or CuCN (10 mol %) in conjunction with BF_3 and TMS-Cl catalyze addition of alkylzinc bromides to enones.

Several examples of mixed organocopper-zinc reagents in synthesis are given in Scheme 8.5. Entries 1 and 2 show the use of functionalized reagents prepared from the corresponding iodides by reaction with zinc, followed by CuCN-LiCl. Entry 3 uses a similar reagent to prepare a prostaglandin precursor. Note the slightly different pattern from Entry 3 in Scheme 8.4; in the present case the addition is to an exocyclic methylene group rather than to an endocyclic cyclopentenone. Entry 4 involves generation of a mixed reagent directly from an iodide, followed by conjugate addition to methyl acrylate. Entries 5 and 6 are substitutions on allylic systems. The arylzinc reagent used in Entry 5 was prepared from 2-nitrophenyllithium, which was prepared by halogen-metal exchange, as discussed on p. 632. Entry 7 is a stereospecific S_N2' displacement on an allylic methanesulfonate. Entry 8 is a substitution on a β -sulfonyloxy enone. The zinc reagent is mixed dialkyl zinc. This reaction may proceed by conjugate addition to give the enolate, followed by elimination of the triflate group. Entry 9 shows the use of a tertiary mixed zinc reagent in the preparation of a ketone.

8.1.2.6. Carbometallation with Mixed Organocopper Compounds. Mixed copper-magnesium reagents analogous to the lithium cuprates can be prepared.⁷⁴ The precise structural nature of these compounds, often called *Normant reagents*, has not been determined. Individual species with differing Mg:Cu ratios may be in equilibrium.⁷⁵ These reagents undergo addition to terminal acetylenes to generate alkenylcopper reagents. The addition is stereospecifically *syn*.

The alkenylcopper adducts can be worked up by protonolysis, or they can be subjected to further elaboration by alkylation or electrophilic substitution.

Mixed copper-zinc reagents also react with alkynes to give alkenylcopper species that can undergo subsequent electrophilic substitution.

Ref. 76

The mechanism of carbometallation has been explored computationally.⁷⁷ The reaction consists of an oxidative addition to the triple bond forming a cyclic Cu(III) intermediate. The rate-determining step is reductive elimination to form a vinyl magnesium (or zinc) reagent, which then undergoes transmetalation to the alkenyl-copper product.

Some additional examples are given in Scheme 8.6. The electrophiles that have been used successfully include iodine (Entries 2 and 3) and cyanogen chloride (Entry 4). The adducts can undergo conjugate addition (Entry 5), alkylation (Entry 6), or epoxide ring opening (Entries 7 and 8). The latter reaction is an early step of a synthesis of epothilone B.

The lithium cuprate reagents are not as reactive toward terminal alkynes as mixed magnesium or zinc reagents. The stronger Lewis acid character of Mg^{2+} , as compared to Li^+ , is believed to be the reason for the enhanced reactivity of the magnesium reagents. However, lithium dialkylcuprates do react with conjugated acetylenic esters, with *syn* addition being kinetically preferred.⁷⁸

The intermediate adduct can be substituted at the α -position by a variety of electrophiles, including acyl chlorides, epoxides, aldehydes, and ketones.⁷⁹

8.1.2.7. Mechanistic Interpretation of the Reactivity of Organocopper Compounds.

The coupling with halides and tosylates, epoxide ring openings, and conjugate additions discussed in the preceding sections illustrate the nucleophilicity of the organocopper reagents. The nucleophilicity is associated with relatively high-energy filled *d* orbitals that are present in Cu(I), which has a $3d^{10}$ electronic configuration. The role of

Fig. 8.2. Computational energy profile (B3LYP/631A) for reaction of $(\text{CH}_3)_2\text{CuLi-LiCl}$ with CH_3Br including one solvent (CH_3OCH_3) molecule. Adapted from *J. Am. Chem. Soc.*, **122**, 7294 (2000), by permission of the American Chemical Society.

the copper-lithium clusters has been explored computationally (B3LYP/631A) for reactions with methyl bromide,⁸⁰ ethylene oxide,⁸⁰ acrolein,⁸¹ and cyclohexenone.⁸² In the case of methyl bromide, the reaction was studied both with and without a solvation model. The results in the case of inclusion of one molecule of solvent (CH_3OCH_3) are shown in Figure 8.2. The rate-determining step is the conversion of a complex of the reactant cluster, $[(\text{CH}_3)_2\text{CuLi-LiCl}]\text{-CH}_3\text{Br}$, to a tetracoordinate Cu(III) species. The calculated barrier is 13.6 kcal/mol. The reductive elimination step has a very low barrier (~ 5 kcal/mol).

The ring opening of ethylene oxide was studied with CH_3SCH_3 as the solvent molecule and is summarized in Figure 8.3. The crucial TS again involves formation of the C-Cu bond and occurs with assistance from Li^+ . As with methyl bromide, the reductive elimination has a low barrier. Incorporation of BF_3 leads to a structure **TS-XXXi** (insert in Figure 8.3) in which BF_3 assists the epoxide ring opening. The

The insert (**TS-XXXI**) is a TS that incorporates BF_3 , but not $(\text{CH}_3)_2\text{S}$. Adapted from *J. Am. Chem. Soc.*, **122**, 7294 (2000), by permission of the American Chemical Society.

stabilization of the TS leads to a reduction of almost 37 kcal/mol in the computed E_a relative to **TSXXg**.

The nucleophilicity of the organocuprate cluster derives mainly from the filled copper $3d_z^2$ orbital, in combination with the carbon orbital associated with bonding to copper. These orbitals for the TS for reaction with methyl bromide and ethylene oxide are shown in Figure 8.4.

The conjugate addition reaction has also been studied computationally. B3LYP/631A calculations of the reaction of $[(\text{CH}_3)_2\text{CuLi}]_2$ with acrolein gives the TS and intermediates depicted in Figure 8.5.⁸¹ Three intermediates and three TSs are represented. The first structure is a complex of the reactants (**CP1i**), which involves coordination of the acrolein oxygen to a lithium cation in the reactant. The second intermediate (**CPcl**) is a π complex in which the cluster is opened. A key feature of the mechanism is the third intermediate **CPop**, which involves interaction of *both* lithium ions with the carbonyl oxygen. Moreover, in contrast to the reactions with halides and epoxides, it is the *reductive elimination step that is rate determining*. The calculated barrier for this step is 10.4 kcal/mol.

Fig. 8.4. Representation of the orbital involved in C-Cu bond formation in the reaction of $(\text{CH}_3)_2\text{CuLi-LiCl}$ with methyl bromide (left) and ethylene oxide (right). Reproduced from *J. Am. Chem. Soc.*, **122**, 7294 (2000), by permission of the American Chemical Society.

Fig. 8.5. Computational reaction profile (B3LYP/631A) for reaction of $[(\text{CH}_3)_2\text{CuLi}]_2$ with acrolein. Adapted from *J. Am. Chem. Soc.*, **119**, 4900 (1997), by permission of the American Chemical Society.

The role of BF_3 catalysis in the conjugate addition was also explored.⁸³ Inclusion of BF_3 results in a considerable stabilization of the reaction complex, but there is also a lowered barrier for the rate-determining reductive elimination. This suggests that BF_3 functions primarily at the Cu(III) stage by facilitating the decomposition of the Cu(III) intermediate.

A similar sequence of intermediates and TSs was found for the reaction of cyclohexenone.⁸² In this case, both axial and equatorial approaches were examined. At the crucial rate- and product-determining TS for C–C bond formation, the axial pathway is favored by 1.7 kcal/mol, in agreement with experimental results from conformationally biased cyclohexenones. Nearly all of the difference is due to factors in the cyclohexenone ring and transferring methyl group. This result suggests that analysis of stereoselectivity of cuprate conjugate additions should focus on the relative energies of the competing TS for the C–C bond-forming step. These computational studies comport well with a variety of product, kinetic, and spectroscopic studies that have been applied to determining the mechanism of organocuprates and related reagents.⁸⁴

Visual models and additional information on Organocuprate Intermediates can be found in the Digital Resource available at: Springer.com/carey-sundberg.

8.1.2.8. Enantioselective Reactions of Organocopper Reagents. Several methods have been developed for achieving enantioselectivity with organocopper reagents. Chiral auxiliaries can be used; for example, oxazolidinone auxiliaries have been utilized in conjugate additions. The outcome of these reactions can be predicted on the basis of steric control of reactant approach, as for other applications of the oxazolidinone auxiliaries.

Ref. 85

Conjugate addition reactions involving organocopper intermediates can be made enantioselective by using chiral ligands.⁸⁶ Several mixed cuprate reagents containing

epoxide ring-opening reactions are available for the synthesis of alcohols. The reactants for conjugate addition include α,β -unsaturated ketones, esters, amides, and nitriles, and these reactions can be combined with tandem alkylation. These synthetic transformations are summarized below.

8.2. Reactions Involving Organopalladium Intermediates

Organopalladium intermediates are very important in synthetic organic chemistry. Usually, organic reactions involving palladium do not involve the preparation of stoichiometric organopalladium reagents. Rather, organopalladium species are generated *in situ* during the course of the reaction. In the most useful processes only a *catalytic amount* of palladium is used. The overall reaction mechanisms typically involve several steps in which organopalladium species are formed, react with other reagents, give product, and are regenerated in a catalytically active form. Catalytic processes have both economic and environmental advantages. Since, in principle, the catalyst is not consumed, it can be used to make product without generating by-products. Some processes use *solid phase catalysts*, which further improve the economic and environmental advantages of catalyst recovery. Reactions that involve chiral catalysts can generate enantiomerically enriched or pure materials from achiral starting materials. In this section we focus on carbon-carbon bond formation, but in Chapter 11 we will see that palladium can also catalyze aromatic substitution reactions.

Several types of organopalladium intermediates are of primary importance in the reactions that have found synthetic applications. Alkenes react with Pd(II) to give π complexes that are subject to *nucleophilic attack*. These reactions are closely related to the solvomercuration reactions discussed in Section 4.1.3. The products that are formed from the resulting intermediates depend upon specific reaction conditions. The palladium can be replaced by hydrogen under reductive conditions (path a). In the absence of a reducing agent, elimination of Pd(0) and a proton occurs, leading to net substitution of a vinyl hydrogen by the nucleophile (path b). We return to specific examples of these reactions shortly.

A second major group of organopalladium intermediates are π -allyl complexes, which can be obtained from Pd(II) salts, allylic acetates, and other compounds having potential leaving groups in an allylic position.⁹⁸ The same type of π -allyl complex can be prepared directly from alkenes by reaction with PdCl₂ or Pd(O₂CCF₃)₂.⁹⁹ The reaction with alkenes occurs by electrophilic attack on the π electrons followed by loss of a proton. The proton loss probably proceeds via an unstable species in which the hydrogen is bound to palladium.¹⁰⁰

These π -allyl complexes are moderately *electrophilic*¹⁰¹ in character and react with a variety of nucleophiles, usually at the less-substituted allylic terminus. After nucleophilic addition occurs, the resulting organopalladium intermediate usually breaks down by elimination of Pd(0) and H⁺. The overall transformation is an allylic substitution.

Another general process involves the reaction of Pd(0) species with halides or sulfonates by *oxidative addition*, generating reactive intermediates having the organic group attached to Pd(II) by a σ bond. The oxidative addition reaction is very useful for aryl and alkenyl halides, but the products from saturated alkyl halides often decompose by β -elimination. The σ -bonded species formed by oxidative addition can react with alkenes and other unsaturated compounds to form new carbon-carbon bonds. The

¹⁰⁰. D. R. Chrisope, P. Beak, and W. H. Saunders, Jr., *J. Am. Chem. Soc.*, **110**, 230 (1988).

¹⁰¹. O. Kuhn and H. Mayr, *Angew. Chem. Int. Ed. Engl.*, **38**, 343 (1998).

σ -bound species also react with a variety of organometallic reagents to give coupling products.

These are called *cross-coupling reactions* and usually involve three basic steps: oxidative addition, transmetallation, and reductive elimination. In the transmetallation step an organic group is transferred from the organometallic reagent to palladium.

The organometallic reagents that give such reactions include organomagnesium, organolithium, and organozinc compounds, stannanes, and even organoboron compounds. The reactions are very general for sp^2 - sp^2 and sp^2 - sp coupling and in some systems can also be applied to sp^2 - sp^3 coupling. Most of these procedures involve phosphine or related ligands.

Organopalladium intermediates are also involved in the synthesis of ketones and other carbonyl compounds. These reactions involve acylpalladium intermediates, which can be made from acyl halides or by reaction of an organopalladium species with carbon monoxide. A second organic group, usually arising from any organometallic reagent, can then form a ketone. Alternatively, the acylpalladium intermediate may react with nucleophilic solvents such as alcohols to form esters.

In considering the mechanisms involved in organopalladium chemistry, several general points should be kept in mind. Frequently, reactions involving organopalladium

intermediates are done in the presence of phosphine ligands, which play a key role by influencing the reactivity at palladium. Another general point concerns the relative weakness of the C–Pd bond and, especially, the instability of alkylpalladium species in which there is a β -hydrogen.

The final stage in many palladium-mediated reactions is the elimination of Pd(0) and H⁺ to generate a carbon-carbon double bond. This tendency toward elimination distinguishes organopalladium species from most of the organometallic species we have discussed up to this point. Finally, organopalladium(II) species with two organic substituents show the same tendency to react with recombination of the organic groups by reductive elimination that is exhibited by copper(III) intermediates. This reductive elimination generates the new carbon-carbon bond.

8.2.1. Palladium-Catalyzed Nucleophilic Addition and Substitution

8.2.1.1. The Wacker Reaction and Related Oxidations. An important industrial process based on Pd-alkene complexes is the *Wacker reaction*, a catalytic method for conversion of ethene to acetaldehyde. The first step is addition of water to the Pd(II)-activated alkene. The addition intermediate undergoes the characteristic elimination of Pd(0) and H⁺ to generate the enol of acetaldehyde.

The reaction is run with only a catalytic amount of Pd. The co-reagents CuCl₂ and O₂ serve to reoxidize the Pd(0) to Pd(II). The net reaction consumes only alkene and oxygen.

The relative reactivity profile of the simple alkenes toward Wacker oxidation is quite shallow and in the order ethene > propene > 1-butene > *E*-2-butene > *Z*-2-butene.¹⁰² This order indicates that steric factors outweigh electronic effects and is consistent with substantial nucleophilic character in the rate-determining step. (Compare with oxymercuration; see Part A, Section 5.8.) The addition step is believed to occur by an internal ligand transfer through a four-center mechanism, leading to *syn* addition.

The stereochemistry, however, is sensitive to the concentration of chloride ion, shifting to *anti* when chloride is present.¹⁰³

The Wacker reaction can also be applied to laboratory-scale syntheses.¹⁰⁴ When the Wacker conditions are applied to terminal alkenes, methyl ketones are formed.¹⁰⁵

This regiochemistry is consistent with the electrophilic character of Pd(II) in the addition step. Solvent and catalyst composition can affect the regiochemistry of the Wacker reaction. Use of *t*-butanol as the solvent was found to increase the amount of aldehyde formed from terminal alkenes, and is attributed to the greater steric requirement of *t*-butanol. Hydrolysis of the enol ether then leads to the aldehyde.

These conditions are particularly effective for allyl acetate.¹⁰⁶

Both the regiochemistry and stereochemistry of Wacker oxidation can be influenced by substituents that engage in chelation with Pd. Whereas a single γ -alkoxy function leads to a mixture of aldehyde and ketone, more highly oxygenated systems such as the acetonide or carbonate of the diol **1** lead to dominant aldehyde formation.¹⁰⁷ The diol itself gives only ketone, which perhaps indicates that steric factors are also important.

The two reactions shown below are examples of the use of the Wacker reaction in multistep synthesis. In the first case, selectivity is achieved between two terminal alkene units on the basis of a difference in steric accessibility. Both reactions use a reduced amount of Cu(I) salt. In the second reaction this helps to minimize hydrolysis of the acid-sensitive dioxolane ring.

Palladium(II) like Hg(II) can induce intramolecular nucleophilic addition, but this is followed by elimination of Pd(0) and H⁺. For example, γ , δ - and δ , ϵ -unsaturated carboxylic acids can be cyclized to unsaturated lactones by Pd(OAc)₂ in DMSO in the presence of O₂. Although Cu(OAc)₂ can be included as a catalyst for reoxidation of the Pd(0), it is not necessary.¹¹⁰

Similarly, phenols with unsaturated side chains can form five- and six-membered rings. In these systems the quaternary carbon imposes the β , γ -elimination. As with the above

cyclization, a copper co-oxidant is not needed. The pyridine is evidently involved in accelerating the oxidation of Pd(0) by O₂.¹¹¹

Cyclizations of this type can be carried out with high enantioselectivity using a chiral *bis*-oxazoline catalyst.

Ref. 112

A deuterium-labeling study of a reaction of this type demonstrated *syn* stereoselectivity in both the oxypalladation and β -elimination, which indicates that the cyclization occurs by internal migration, rather than by an *anti* nucleophilic capture.¹¹³ This particular system also gives products from double-bond migration that occurs by reversible Pd(II)–D addition-elimination.

8.2.1.2. Nucleophilic Substitution of π -Allyl Palladium Complexes. π -Allyl palladium species are subject to a number of useful reactions that result in allylation of nucleophiles.¹¹⁴ The reaction can be applied to carbon-carbon bond formation using relatively stable carbanions, such as those derived from malonate esters and β -sulfonyl esters.¹¹⁵ The π -allyl complexes are usually generated in situ by reaction of an allylic acetate with a catalytic amount of *tetrakis*-(triphenylphosphine)palladium

or a chelated diphosphine complex.¹¹⁶ The reactive Pd(0) species is regenerated in an elimination step.

Ref. 117

For unsymmetrical allylic systems both the regiochemistry and stereochemistry of the substitution are critical issues. The palladium normally bonds *anti* to the acetate leaving group. The same products are obtained from 2-acetoxy-4-phenyl-3-butene and 1-acetoxy-1-phenyl-2-butene, indicating a common intermediate. The same product mixture is also obtained from the *Z*-reactants, indicating rapid *E,Z*-equilibration in the allylpalladium intermediate.¹¹⁸

In the presence of chiral phosphine ligands, there is also rapid epimerization to the most stable diastereomeric π -allyl complex. The stereoselectivity arises in the reaction with the nucleophile.¹¹⁹

Mechanistically, the nucleophilic addition can occur either by internal ligand transfer or by external attack. Generally, softer more stable nucleophiles (e.g., malonate enolates) are believed to react by the external mechanism and give *anti* addition, whereas harder nucleophiles (e.g., hydroxide) are delivered by internal ligand transfer with *syn* stereochemistry.¹²⁰

Both the regiochemistry and stereochemistry are influenced by reaction conditions. A striking example is a complete switch to 3-alkylation of dimethyl malonate

anion by 1-phenylprop-2-enyl acetate in the presence of iodide ion. In the absence of iodide, using 2 mol % catalyst, the ratio of **2** to **3** is about 4:1. When 2 mol % iodide is added, only **2** is formed. This change is attributed to the involvement of a catalytic species in which I^- is present as a Pd ligand. The effect is diminished when a chelating diphosphine ligand is used, presumably because addition of I^- to the Pd ligand sphere is prevented by the chelate.

Ref. 121

The allylation reaction has also been used to form rings. β -Sulfonyl esters have proven particularly useful in this application for formation of both medium and large rings.¹²² In some cases medium-sized rings are formed in preference to six- and seven-membered rings.¹²³

The sulfonyl substituent can be removed by reduction after the ring closure (see Section 5.6.2). Other appropriate reactants are α -phenylthio nitriles, which can be hydrolyzed to lactones.¹²⁴

Allylation reactions can be made highly enantioselective by the use of various chiral phosphine ligands.¹²⁵ Examples are included in Scheme 8.8.

8.2.2. The Heck Reaction

Another important type of reactivity of palladium, namely oxidative addition to Pd(0), is the foundation for several methods of forming carbon-carbon bonds. Aryl¹²⁶ and alkenyl¹²⁷ halides react with alkenes in the presence of catalytic amounts of palladium to give net substitution of the halide by the alkenyl group. The reaction, known as the *Heck reaction*,¹²⁸ is quite general and has been observed for simple alkenes, aryl-substituted alkenes, and substituted alkenes such as acrylate esters, vinyl ethers, and *N*-vinylamides.¹²⁹

Org. Chem.*, **43**, 2949 (1978); H. A. Dieck and R. F. Heck, *J. Am. Chem. Soc.*, **96**, 1133 (1974); C. A. Busacca, R. E. Johnson, and J. Swestock, *J. Org. Chem.*, **58**, 3299 (1993).

Many procedures use $\text{Pb}(\text{OAc})_2$ or other $\text{Pd}(\text{II})$ salts as catalysts with the catalytically active $\text{Pd}(0)$ being generated in situ. The reactions are usually carried out in the presence of a phosphine ligand, with *tris-o*-tolylphosphine being preferred in many cases. *Tris*-(2-furyl)phosphine (tfp) is also used frequently. Several chelating diphosphines, shown below with their common abbreviations, are also effective. Phosphites are also good ligands.¹³⁰

The reaction is initiated by oxidative addition of the halide or sulfonate to a $\text{Pd}(0)$ species generated in situ from the $\text{Pd}(\text{II})$ catalyst. The arylpalladium(II) intermediate then forms a π complex with the alkene, which rearranges to a σ complex by carbon-carbon bond formation. The σ complex decomposes by β -elimination with regeneration of $\text{Pd}(0)$. Both of these reactions occur with *syn* stereoselectivity. The Heck reaction often uses of $\text{Pd}(\text{OAc})_2$ as the palladium source along with a triarylphosphine and a tertiary amine. Under these conditions it has been proposed that the initiation of the reaction involves formation of an anionic complex $[\text{Pd}(\text{L})_2\text{OAc}]^-$.¹³¹ This is a 16-electron species and is considered to be the active form of Pd for the oxidative addition. The base is crucial in maintaining the equilibrium in favor of the active anionic form after the reductive elimination. This is called the *anionic mechanism*. Note that the phosphine ligand is also the reducing agent for formation of the active $\text{Pd}(0)$ species.

¹³⁰ M. Beller and A. Zapt, *Synlett*, 792 (1998).

¹³¹ A. Amatore and A. Jutand, *Acc. Chem. Res.*, **33**, 314 (2000).

Several different Pd(0) species can be involved in both the oxidative addition and π -coordination steps, depending on the anions and ligands present. Because of the equilibria involving dissociation of phosphine ligands and anions, there is dependence on their identity and concentration.¹³² High halide concentration promotes formation of the anionic species $[\text{PdL}_2\text{X}]^-$ by addition of a halide ligand. Use of trifluoromethanesulfonate anions promotes dissociation of the anion from the Pd(II) adduct and accelerates complexation with electron-rich alkenes. The presence of metal ions that bind the halide, e.g., Ag^+ , also promotes dissociation. Reactions that proceed through a dissociated species are called *cationic* and are expected to have a more electrophilic interaction with the alkene. A base is included to neutralize the proton released in the β -elimination step. The catalytic cycle under these conditions is shown below.

It appears that a modified mechanism operates when *tris*-(*o*-tolyl)phosphine is used as the ligand,¹³³ and this phosphine has been found to form a *palladacycle*. Much more stable than noncyclic Pd(0) complexes, this compound is also more reactive toward oxidative addition. As with the other mechanisms, various halide adducts or halide-bridged compounds may enter into the overall mechanism.

Several modified reaction conditions have been developed. One involves addition of silver salts, which activate the halide toward displacement.¹³⁴ Use of sodium bicarbonate or sodium carbonate in the presence of a phase transfer catalyst permits especially mild conditions to be used for many systems.¹³⁵ Tetraalkylammonium salts also often accelerate reaction.¹³⁶ Solid phase catalysts in which the palladium is complexed by polymer-bound phosphine groups have also been developed.¹³⁷

Aryl chlorides are not very reactive under normal Heck reaction conditions but reaction can be achieved by inclusion of tetraphenylphosphonium salts with $\text{Pd}(\text{OAc})_2$ or PdCl_2 as the catalysts.¹³⁸

Pretreatment with nickel bromide causes normally unreactive aryl chlorides to undergo Pd-catalyzed substitution,¹³⁹ and aryl and vinyl triflates have been found to be excellent substrates for Pd-catalyzed alkenylations.¹⁴⁰

Heck reactions can be carried out in the absence of phosphine ligands.¹⁴¹ These conditions usually involve $\text{Pd}(\text{OAc})_2$ as a catalyst, along with a base and a phase transfer salt such as tetra-*n*-butylammonium bromide. These conditions were originally applied to stereospecific coupling of vinyl iodides with ethyl acrylate and methyl vinyl ketone.

Several optimization studies have been carried out under these phosphine-free conditions. The reaction of bromobenzene and styrene was studied using $\text{Pd}(\text{OAc})_2$ as the catalyst, and potassium phosphate and *N,N*-dimethylacetamide (DMA) were found to be the best base and solvent. Under these conditions, the Pd content can be reduced to as low as 0.025 mol %.¹⁴² The reaction of substituted bromobenzenes with methyl α -acetamidoacrylate has also been studied carefully, since the products are potential precursors of modified amino acids. Good results were obtained using either *N,N*-diisopropylethylamine or NaOAc as the base.

Ref. 143

Low Pd concentrations are beneficial in preventing precipitation of inactive Pd metal.¹⁴⁴ Small Pd clusters can be observed in phosphine-free systems,¹⁴⁵ and these particles may serve as catalysts or, alternatively, as reservoirs of Pd for formation of soluble reactive species.

The regiochemistry of the Heck reaction is determined by the competitive removal of the β -proton in the elimination step. Mixtures are usually obtained if more than one type of β -hydrogen is present. Often there is also double-bond migration that occurs by reversible Pd-H elimination-addition sequences. For example, the reaction of cyclopentene with bromobenzene leads to all three possible double-bond isomers.¹⁴⁶

Substituents with stronger electronic effects can influence the competition between α - and β -arylation. Alkenes having EWG substituents normally result in β -arylation. However, alkenes with donor substituents give a mixture of α - and β -regioisomers. The regiochemistry can be controlled to some extent by specific reaction conditions. Bidentate phosphines such as dppp and dppe promote α -arylation of alkenes with donor substituents such as alkoxy, acetoxy, and amido. These reactions are believed to occur through the more electrophilic form of Pd(II) generated by dissociation of the triflate anion (cationic mechanism).¹⁴⁷ Electronic factors favor migration of the aryl group to the α -carbon. The combination of the bidentate ligand and triflate leaving group increases the importance of electronic effects on the regiochemistry.

Substituents without strong donor or acceptor character (e.g., phenyl, succinimido) give mixtures. The reason for the increased electronic sensitivity is thought to be the

involvement of a cationic, as opposed to a neutral, complex. The triflate anion is more likely to be dissociated than a halide.

Allylic silanes show a pronounced tendency to react at the α -carbon in the presence of bidentate ligands.¹⁴⁸ This regiochemistry is attributed to the preferential stabilization of cationic character by the silyl substituent. The bidentate ligands enhance the electrophilic character of the TS, and the cation stabilization of the silyl group becomes the controlling factor.

There have been several computational studies of electronic effects on the regioselectivity of the Heck reaction. Vinyl migration was studied for $X = \text{CH}_3$, CN , and OCH_3 using PH_3 as the ligand model.¹⁴⁹ Differences were calculated for the best α - and β -migration TS for each substituent. The differences were as follows: CH_3 : α -migration favored by 0.1 kcal/mol; CN : β -migration favored by 4 kcal/mol; OCH_3 : α -migration favored by 2 kcal/mol.

Examination of the HOMO and LUMO orbitals in these TSs indicates that the electronic effect operates mainly through the LUMO. The EWG cyano tends to localize the LUMO on the β -carbon, whereas ERG substituents have the opposite effect. Similar trends were found for Pd coordinated by diimine ligands.¹⁵⁰ These results indicate that the Markovnikov rule applies with the more electrophilic Pd complexes. When steric effects become dominant, the Pd adds to the less hindered position.

The Heck reaction has been applied to synthesis of intermediates and in multi-stage syntheses. Some examples are given in Scheme 8.9. Entries 1 and 2 illustrate both the β -regioselectivity and selectivity for aryl iodides over bromides. Entries 3 and 4 show conditions that proved favorable for cyclohexene. These examples also indicate preferential *syn* Pd-H elimination, since this accounts for formation of the 3-substituted cyclohexene as the major product.

Entry 5 illustrates use of a vinyl triflate under the “phosphine-free” conditions. Entry 6 achieved exceptionally high catalyst efficiency by using a palladacycle-type catalyst. Entries 7 and 8 show the introduction of acrylate ester groups using functionalized alkenyl iodides. Entry 9 demonstrates two successive Heck reactions employed in a large-scale synthesis of a potential thromboxane receptor antagonist. These reactions were carried out in the absence of any phosphine ligand. The greater reactivity of the iodide over the bromide permits the sequential introduction of the two substituents.

There are numerous examples of intramolecular Heck reactions,¹⁵¹ such as in Entries 10 to 14. Entry 11 is part of a synthesis of the antitumor agent camptothecin. The Heck reaction gives an 11:1 endocyclic-exocyclic mixture. Entries 12–14 are also steps in syntheses of biologically active substances. Entry 12 is part of a synthesis of maritidine, an alkaloid with cytotoxic properties; the reaction in Entry 13 is on a route to galanthamine, a potential candidate for treatment of Alzheimer’s disease; and Entry 14 is a key step in the synthesis of a potent antitumor agent isolated from a marine organism.

8.2.3. Palladium-Catalyzed Cross Coupling

Palladium can catalyze carbon-carbon bond formation between aryl or vinyl halides and sulfonates and a wide range of organometallic reagents in *cross-coupling reactions*.¹⁵² The organometallic reagents used include organolithium, organomagnesium, and organozinc reagents, as well as cuprates, stannanes, and organoboron compounds. The reaction is quite general for formation of sp^2 - sp^2 and sp^2 - sp bonds in biaryls, dienes, polyenes, and enynes. There are also some reactions that can couple alkyl organometallic reagents, but these are less general because of the tendency of alkylpalladium intermediates to decompose by β -elimination. Arylation of enolates also can be effected by palladium catalysts.

The basic steps in the cross-coupling reaction include oxidative addition of the aryl or vinyl halide (or sulfonate) to Pd(0), followed by transfer of an organic group from the organometallic to the resulting Pd(II) intermediate (*transmetallation*). The disubstituted Pd(II) intermediate then undergoes reductive elimination, which gives the product by carbon bond formation and regenerates the catalytically active Pd(0) oxidation level.

¹⁵² F. Diederich and P. J. Stang, *Metal-Catalyzed Cross-Coupling Reactions*, Wiley-VCH, New York, 1998; S. P. Stanforth, *Tetrahedron*, **54**, 263 (1998).

Ligands and anions play a crucial role in determining the rates and equilibria of the various steps by controlling the detailed coordination environment at palladium.¹⁵³ In the next section we discuss coupling reactions involving organolithium, organomagnesium, organozinc, and organocopper reagents. We then proceed to arylation of enolates mediated by palladium catalysts. Subsequent sections consider cross coupling with stannanes (*Stille reaction*) and boron compounds (*Suzuki reaction*).

8.2.3.1. Coupling with Organometallic Reagents. *Tetrakis*-(triphenylphosphine) palladium catalyzes coupling of alkenyl halides with Grignard reagents and organolithium reagents. The reactions proceed with retention of configuration at the double bond.

Organozinc compounds are also useful in palladium-catalyzed coupling with aryl and alkenyl halides. Procedures for arylzinc,¹⁵⁶ alkenylzinc,¹⁵⁷ and alkylzinc¹⁵⁸ reagents have been developed. The ferrocenyldiphosphine *dppf* has been found to be an especially good Pd ligand for these reactions.¹⁵⁹

Scheme 8.10 shows some representative coupling reactions with organomagnesium and organozinc reagents. Entry 1 shows a biaryl coupling accomplished using an arylzinc reagent. Entry 2 involves the use of a chelating ligand with an aryl triflate. The *bis*-phosphines *dppe*, *dppp*, and *dppb* were also effective for this coupling. Entry 3 is an example of use of a vinyl triflate. Entries 4 and 5 illustrate the use of perfluorobutanesulfonate (nonaflate) as an alternative leaving group to triflate. The organozinc

reagent in Entry 4 was prepared by the hydroboration route (see Section 7.3.1.1). The reaction in Entry 7 was used to prepare analogs of the pyrethrin insecticides. There was a substantial difference in the reactivity of the two chlorides, permitting the stereoselective synthesis.

There are a number of procedures for coupling of terminal alkynes with halides and sulfonates, a reaction that is known as the *Sonogashira reaction*.¹⁶¹ A combination of $\text{Pd}(\text{PPh}_3)_4$ and $\text{Cu}(\text{I})$ effects coupling of terminal alkynes with vinyl or aryl halides.¹⁶² The reaction can be carried out directly with the alkyne, using amines for deprotonation. The alkyne is presumably converted to the copper acetylide, and the halide reacts with $\text{Pd}(0)$ by oxidative addition. Transfer of the acetylide group to Pd results in reductive elimination and formation of the observed product.

The original conditions used amines as solvents or cosolvents. Several other bases can replace the amine. Tetrabutylammonium hydroxide or fluoride can be used in THF (see Entry 1 in Scheme 8.11).¹⁶³ Tetrabutylammonium acetate is also effective with aryl iodides and EWG-substituted aryl bromides (Entry 2).¹⁶⁴ Use of alkenyl halides in this reaction has proven to be an effective method for the synthesis of enynes¹⁶⁵ (see also Entries 5 and 6 in Scheme 8.11).

Ref. 166

Several hindered phosphine ligands give enhanced reactivity. Aryl iodides can be coupled at low temperature using $\text{Pd}_2(\text{dba})_3$ and *tris*-(mesityl)phosphine.

Ref. 167

$\text{Pd}_2(\text{dba})_3$ with *tris*-*t*-butylphosphine is an effective catalyst and functions in the absence of copper.¹⁶⁸

Ref. 170

8.2.3.2. Palladium-Catalyzed Arylation of Enolates. Very substantial progress has been made in the use of Pd-catalyzed cross coupling for arylation of enolates and enolate equivalents. This reaction provides an important method for arylation of enolates, which is normally a difficult transformation to accomplish.¹⁷¹ A number of phosphine ligands have been found to promote these reactions. Bulky trialkyl phosphines such as *tris*-(*t*-butyl)phosphine with a catalytic amount of Pd(OAc)₂ results in phenylation of the enolates of aromatic ketones and diethyl malonate.¹⁷²

Phenylation has also been achieved with the diphosphine ligands BINAP and tol-BINAP.

Ref. 173

Several biphenylphosphines with 2'-amino substituents are also effective in arylation of ester enolates.¹⁷⁴ Among the esters that were successfully arylated were *t*-butyl acetate, *t*-butyl propanoate, and ethyl phenylacetate. The ester enolates were generated with LiHMDS.

¹⁷⁴ W. A. Moradi and S. L. Buchwald, *J. Am. Chem. Soc.*, **123**, 7996 (2001).

Carbenoid imidazolidene ligands such as **C** can also be used in conjunction with $\text{Pd}(\text{dba})_2$, and this method has been applied to α -arylpropanoic acids (NSAIDs) such as naproxen.¹⁷⁵

Highly arylated ketones have been prepared successfully. For example, arylation of the enolate of the deoxybenzoin **4** gives 1,1,2-triarylethanones that are related to substances such as tamoxifen.¹⁷⁶

Similar reactions have been carried out using polymer-supported catalysts.¹⁷⁷

Arylations have also been extended to zinc enolates of esters (Reformatsky reagents).¹⁷⁸

These conditions can also be applied to enolates prepared from α -halo amides.

¹⁷⁸ T. Hama, X. Liu, D. A. Culkin, and J. F. Hartwig, *J. Am. Chem. Soc.*, **125**, 11176 (2003).

Enolate arylation has also been extended to aryl tosylates. The preferred catalyst includes a very bulky biphenyl phosphine **D**.¹⁷⁹

Conditions for arylation of enolate equivalents have also been developed. In the presence of ZnF₂, silyl enol ethers, silyl ketene acetals, and similar compounds react. For example, the TMS derivatives of *N*-acyl oxazolidinones can be arylated.

Arylacetate esters have been generated by coupling aryl bromides with stannyl enolates generated from silyl ketene acetals.

Intramolecular arylations are possible and several studies have examined the synthesis of biologically active compounds such as oxindoles.¹⁸¹ For example, a synthesis of physovenine has been reported using this methodology.

8.2.3.3. *Coupling with Stannanes.* Another important group of cross-coupling reactions, known as *Stille reactions*, uses aryl and alkenyl stannanes as the organometallic component.¹⁸³ The reactions are carried out with Pd(0) catalysts in the presence of phosphine ligands and have proven to be very general with respect to the halides that can be used. Benzylic, aryl, alkenyl, and allylic halides can all be utilized,¹⁸⁴ and the groups that can be transferred from tin include alkyl, alkenyl, aryl, and alkynyl. The approximate order of the effectiveness of transfer of groups from tin is alkynyl > alkenyl > aryl > methyl > alkyl, so unsaturated groups are normally transferred selectively.¹⁸⁵ Subsequent studies have found better ligands, including *tris*-(2-furyl)phosphine¹⁸⁶ and triphenylarsine.¹⁸⁷ Aryl-aryl coupling rates are increased by the presence of a Cu(I) cocatalyst,¹⁸⁸ which has led to a simplified protocol in which Pd-C catalyst, along with CuI and Ph₃As, gives excellent yields of biaryls.

The general catalytic cycle of the Stille reaction involves oxidative addition, transmetalation, and reductive elimination.

The role of the ligands is both to stabilize the Pd(0) state and to “tune” the reactivity of the palladium. The outline mechanism above does not specify many detailed aspects of the reaction that are important to understanding the effect of ligands, added salts, and solvents. Moreover, it does not address the stereochemistry, either in terms of the Pd center (tetracoordinate? pentacoordinate?, *cis*?, *trans*?) or of the reacting carbon groups (inversion?, retention?). Some of these issues are addressed by a more detailed mechanism.¹⁹⁰

¹⁹⁰ P. Espinet and A. Echavarren, *Angew. Chem. Int. Ed. Engl.*, **43**, 4704 (2004).

The oxidative addition is considered to give a *cis* Pd complex that can rearrange to the more stable *trans* complex. The mechanism also takes account of the possibility of exchange of the ligands by solvent (or anions that may be present). This mechanism suggests that the transmetalation can occur either with retention (TS-A) or inversion (TS-B), which is consistent with experimental observations of both outcomes. The reductive elimination is believed to occur from a *cis* complex, and the ligands can play a role in promoting this configuration. The ligands can also affect the rate and position of the off-on equilibria. Thus there are several factors that affect the detailed kinetics of the reaction and these can be manipulated in optimization of the reaction conditions. Especially when triflates are used as the electrophilic reactant, added LiCl can have a beneficial effect. The chloride is believed to facilitate the oxidative addition step by reversible formation of an anionic complex that is more nucleophilic than the neutral species. (Compare with the anionic mechanisms for the Heck reaction on p. 716.)¹⁹¹ The harder triflate does not have this effect. Acetate ions can also accelerate the reaction.¹⁹² Copper salts are believed to shift the extent of ligation at the palladium by competing for the phosphine ligand.¹⁹³ The kinetics of Stille reactions catalyzed by triphenylarsine have been studied in some detail.¹⁹⁴ In this system, displacement of an arsine ligand by solvent DMF precedes the transmetalation step.

Various phosphine ligands have been employed. *Tris*-(*t*-butyl)phosphine is an excellent ligand and is applicable to both vinyl and arylstannanes, including sterically hindered ones. Aryl chlorides are reactive under these conditions.¹⁹⁵

The Stille reaction can be used with alkenyl stannanes, alkenyl halides, and triflates,¹⁹⁶ and the reactions occur with retention of configuration at both the halide and stannane. These methods are applicable to stereospecific syntheses of materials such as the retinoids.¹⁹⁷

Carotene has been synthesized from a symmetrical 1,10-bis-(tri-*n*-butyl stannyl) decapentaene.¹⁹⁸

The versatility of Pd-catalyzed coupling of stannanes has been extended by the demonstration that alkenyl triflates are also reactive.¹⁹⁹

The alkenyl triflates can be prepared from ketones,²⁰⁰ and methods are available for regioselective preparation of alkenyl triflates from unsymmetrical ketones.²⁰¹

The coupling reaction can tolerate a number of functional groups, as illustrated by a step in the synthesis of the antibiotic nisamycin.

The Stille coupling reaction is very versatile with respect to the functionality that can be carried in both the halide and the tin reagent. Groups such as ester, nitrile, nitro, cyano, and formyl can be present, which permits applications involving “masked functionality.” For example, when the coupling reaction is applied to 1-alkoxy-2-butenylstannanes, the double-bond shift leads to a vinyl ether that can be hydrolyzed to an aldehyde.

Alkenylstannanes react with 1,1-dibromoalkenes to give enynes.²⁰⁴ These reactions are thought to involve elimination of the elements of HBr prior to reductive elimination.

This reaction has been used in the synthesis of a portion of callipeltoside, a substance with anticancer activity.

Ref. 205

The most problematic cases for the Stille reaction involve coupling saturated systems. The tendency for β -elimination of alkylpalladium compounds requires special conditions. *Bis*-(dialkylamino)cyclohexylphosphines have shown considerable success

in promoting coupling of saturated primary bromides and iodides with alkenyl and aryl stannanes.²⁰⁶

The Stille reaction has been successfully applied to a number of macrocyclic ring closures.²⁰⁷ In a synthesis of amphidinolide A, the two major fragments were coupled via a selective Stille reaction, presumably governed by steric factors. After deprotection the ring was closed by coupling the second vinyl stannane group with an allylic acetate.²⁰⁸

A similar cross-coupling reaction was used for macrocyclization in the synthesis of rhizoxin A.²⁰⁹

²⁰⁹. I. S. Mitchell, G. Pattenden, and J. P. Stonehouse, *Tetrahedron Lett.*, **43**, 493 (2002).

A striking example of a macrocyclic closure is found in the double “stitching” done in the final step of the synthesis of the immunosuppressant rapamycin. *Bis*-1,2-(tri-*n*-butylstannyl)ethene reacted with the diiodide to close a 31-membered ring in 28% yield at 70% conversion. The intermediate iodostannane (from a single coupling) was also isolated in about 30% yield and could be cyclized in a second step.²¹⁰

Some other examples of Pd-catalyzed coupling of organostannanes with halides and triflates are given in Scheme 8.12. Entries 1 and 2 are early examples that show that the reaction can be done with either ERG or EWG substituents on the aromatic ring. Entry 3 is an example of the use of an aryl triflate. Entry 5 was developed in the exploration of the synthetic potential of cyclobutendiones. Entries 6 to 11 are various alkenyl-alkenyl and alkenyl-aryl couplings using iodides and triflates. Entries 12 to 14 involve heterocyclic structures in the synthesis of several antibiotics. Entry 15 involves coupling of a protected glycoside with a vinyl triflate and an α -oxystannane. Entry 16 involves an alkynylstannane and generates a deca-1,6-diyne ring. Entries 17 and 18 show the use of allylic and benzylic bromides.

Procedures for the synthesis of ketones based on coupling of organostannanes with acyl halides have also been developed.²¹¹ The catalytic cycle is similar to that involved in coupling with aryl halides. The scope of compounds to which the reaction is applicable includes tetra-*n*-butylstannane. This example indicates that the reductive elimination step competes successfully with β -elimination.

Scheme 8.13 gives some examples of these reactions.

second organic group by transmetallation, and the disubstituted Pd(II) intermediate then undergoes reductive elimination. It appears that either the oxidative addition or the transmetallation can be rate determining, depending on reaction conditions.²¹⁶ With boronic acids as reactants, base catalysis is normally required and is believed to involve the formation of the more reactive boronate anion in the transmetallation step.²¹⁷

In some synthetic applications, specific bases such as Cs_2CO_3 ²¹⁸ or TlOH ²¹⁹ have been found preferable to NaOH . Cesium fluoride can play a similar function by forming fluoroborate anions.²²⁰ In addition to aryl halides and triflates, aryl diazonium ions can be the source of the electrophilic component in coupling with arylboronic acids.²²¹ Conditions for effecting Suzuki coupling in the absence of phosphine ligands have been developed.²²² One of the potential advantages of the Suzuki reaction, especially when boronic acids are used, is that the boric acid is a more innocuous by-product than the tin-derived by-products generated in Stille-type couplings.

Alkenylboronic acids, alkenyl boronate esters, and alkenylboranes can be coupled with alkenyl halides by palladium catalysts to give dienes.²²³

These reactions proceed with retention of double-bond configuration in both the boron derivative and the alkenyl halide. The oxidative addition by the alkenyl halide, transfer

Alkyl substituents on boron in 9-BBN derivatives can be coupled with either vinyl or aryl halides through Pd catalysts.^{224b} This is an especially interesting reaction because of its ability to effect coupling of saturated alkyl groups. Palladium-catalyzed couplings of alkyl groups by most other methods often fail because of the tendency for β -elimination

One catalyst that has been found amenable to alkyl systems is $\text{CH}_3\text{P}(t\text{-Bu})_2$ or the corresponding phosphonium salt.²²⁸ A range of substituted alkyl bromides were coupled with arylboronic acids.

Suzuki couplings have been used in the synthesis of complex molecules. For example, coupling of two large fragments of the epothilone A structure was accomplished in this way.²²⁹

A portion of the side chain of calyculin was prepared by a tandem reaction sequence that combined an alkenylzinc reagent with 2-bromoethenylboronate, followed by Suzuki coupling with a vinyl iodide in the same pot.²³⁰

There are also several examples of the use of Suzuki reactions in scale-up synthesis of drug candidates. In the synthesis of CI-1034, an endothelin antagonist, a triflate,

and boronic acid were coupled in 95% yield on an 80-kg scale.²³¹ For reasons of cost, a replacement was sought for the triflate group, and the most promising was the 4-fluorobenzenesulfonate.

A coupling of a 3-pyridylborane was used in the synthesis of a potential CNS agent.²³² The product (278 kg) was isolated in 92.5% yield as the methanesulfonate salt.

Scheme 8.14 gives some examples of cross coupling using organoboron reagents. Entries 1 to 3 illustrate biaryl coupling. The conditions in Entry 1 are appropriate for the relatively unreactive chlorides. The conditions in Entries 2 and 3 involve no phosphine ligands. The reactions in Entries 4 and 5 illustrate the use of diazonium ions as reactants. Entry 6 illustrates the use of highly substituted reactants. Entry 7 involves use of a cyclic boronate ester. Entries 8 and 9 pertain to heteroaromatic rings. Entry 10 shows the use of a solid-supported reactant. Part B of Scheme 8.14 illustrates several couplings of alkenylboron reagents including catecholboranes (Entries 11 and 12), boronate esters (Entry 13), and boronic acids (Entries 14 and 15). The latter reaction was applied to the synthesis of a retinoate ester. Entry 16 employs a lactone-derived triflate. Entries 17 to 20 are examples of the use of Suzuki couplings in multistage synthesis. Entries 21 to 24 illustrate the applicability of the reaction to alkylboranes. Entry 25 applies phosphine-free conditions to an allylic bromide.

Ketones can also be prepared by palladium-catalyzed reactions of boranes or boronic acids with acyl chlorides. Both saturated and aromatic acyl chlorides react with trialkylboranes in the presence of Pd(PPh₃)₄.²³³

Aromatic acyl chlorides also react with arylboronic acids to give ketones.²³⁴

α,β -Unsaturated acyl chlorides can also be converted to ketones by reaction with arylboronic acids.²³⁵

Ketones can also be prepared directly from carboxylic acids by activation as mixed anhydrides by dimethyl dicarbonate.²³⁶ These conditions were used successfully with alkanolic and alkanedioic acids, as well as aromatic acids.

In all these reactions, the acylating reagent reacts with the active Pd(0) catalyst to give an acyl Pd(II) intermediate. Transmetalation by the organoboron derivative and reductive elimination generate the ketone.

²³⁶ R. Kakino, H. Narahashi, I. Shimizu, and A. Yamamoto, *Bull. Chem. Soc. Jpn.*, **75**, 1333 (2002).

Ketones can also be prepared from 4-methylphenylthiol esters. These reactions require a stoichiometric amount of a Cu(I) salt and the thiophene-2-carboxylate was used.²³⁷

The copper salt is believed to function by promoting the transmetallation stage.

These reaction conditions were applicable to the thiol esters of alkanolic, heteroaromatic, and halogenated acetic acids.

8.2.4. Carbonylation Reactions

Carbonylation reactions involve coordination of carbon monoxide to palladium and a transfer of an organic group from palladium to the coordinated carbon monoxide.

Carbonylation reactions have been observed using both Pd(II)-alkene complexes and σ -bonded Pd(II) species formed by oxidative addition. Under reductive conditions, the double bond can be *hydrocarbonylated*, resulting in the formation of a carboxylic acid or ester.²³⁸ In nucleophilic solvents, the intermediate formed by *solvopalladation* is intercepted by carbonylation and addition of nucleophilic solvent. In both types of reactions, regioisomeric products are possible.

²³⁷. L. S. Liebeskind and J. Srogl, *J. Am. Chem. Soc.*, **122**, 11260 (2000).

²³⁸. B. El Ali and H. Alper, in *Handbook of Organopalladium Chemistry for Organic Synthesis*, Vol. 2, E. Negishi and A. de Meijere, eds., Wiley-Interscience, New York, 2000, pp. 2333–2349.

8.2.4.1. Hydrocarbonylation. The hydrocarbonylation reaction can be applied to the synthesis of α -arylpropanoic acids of the NSAIDS type.²³⁹ For this synthesis to be effective, selective carbonylation of the more-substituted sp^2 carbon is required. Although many carbonylation conditions are unselective, $PdCl_2(PPh_3)_2$ with *p*-toluenesulfonic acid and LiCl achieves excellent selectivity. The selectivity is thought to involve the formation of a benzylic chloride intermediate.

Naproxen can be synthesized in 89% yield with 97.5% regioselectivity under these conditions.

This reaction has been done with good enantioselectivity using 1, 1'-binaphthyl-2, 2'-diyl hydrogen phosphate (BNPPA) as a chiral ligand.²⁴⁰

When conducting hydrocarbonylations with dienes, it was found that a mixture of nonchelating and bidentate phosphine ligands was beneficial.²⁴¹

²³⁹. A. Seayad, S. Jayasree, and R. V. Chaudhari, *Org. Lett.*, **1**, 459 (1999).

²⁴⁰. H. Alper and N. Hamel, *J. Am. Chem. Soc.*, **112**, 2803 (1990).

²⁴¹. G. Vasapollo, A. Somasunderam, B. El Ali, and H. Alper, *Tetrahedron Lett.*, **35**, 6203 (1994).

In some cases double-bond migration was noted, as for isoprene.

Esters can be formed when the hydrocarboxylation reaction is carried out in an alcohol.²⁴² Although hydrocarboxylation is the basis for conversion of alkenes to carboxylic acids on an industrial scale, it has seen only limited application in laboratory synthesis.

Olefin hydrocarboxylation can be used in conjunction with oxidative addition to prepare indanones and cyclopentenones, but the reaction is limited to terminal alkenes.²⁴³

8.2.4.2. Solvocarbonylation. In solvocarbonylation, a substituent is introduced by a nucleophilic addition to a π complex of the alkene. The acylpalladium intermediate is then captured by a nucleophilic solvent such as an alcohol. A catalytic process that involves Cu(II) reoxidizes Pd(0) to the Pd(II) state.²⁴⁴

²⁴² S. Oi, M. Nomura, T. Aiko, and Y. Inoue, *J. Mol. Catal. A.*, **115**, 289 (1997).

²⁴³ S. V. Gagnier and R. C. Larock, *J. Am. Chem. Soc.*, **125**, 4804 (2003).

²⁴⁴ D. E. James and J. K. Stille, *J. Am. Chem. Soc.*, **98**, 1810 (1976).

This reaction has been shown to proceed with overall *anti* addition in the case of *E*- and *Z*-butene.²⁴⁵

Organopalladium(II) intermediates generated from halides or triflates by oxidative addition react with carbon monoxide in the presence of alcohols to give carboxylic acids²⁴⁶ or esters.²⁴⁷

The carbonyl insertion step takes place by migration of the organic group from the metal to the coordinated carbon monoxide, generating an acylpalladium species. This intermediate can react with nucleophilic solvent, releasing catalytically active Pd(0).

The detailed mechanisms of such reactions have been shown to involve addition and elimination of phosphine ligands. The efficiency of individual reactions can often be improved by careful choice of added ligands.

Allylic acetates and phosphates can be readily carbonylated.²⁴⁸ Carbonylation usually occurs at the less-substituted end of the allylic system and with inversion of configuration in cyclic systems.

The reactions are accelerated by bromide salts, which are thought to exchange for acetate in the π -allylic complex. The reactions of acyclic compounds occur with minimal *E*:*Z* isomerization. This result implies that the π -allyl intermediate is captured by carbonylation faster than *E*:*Z* isomerization occurs.

²⁴⁸. S. Murahashi, Y. Imada, Y. Taniguchi, and S. Higashiura, *J. Org. Chem.*, **58**, 1538 (1993).

Coupling of organostannanes with halides in a carbon monoxide atmosphere leads to ketones by incorporation of a carbonylation step.²⁴⁹ The catalytic cycle is similar to that involved in the coupling of alkyl or aryl halides. These reactions involve a migration of one of the organic substituents to the carbonyl carbon, followed by reductive elimination.

This method can also be applied to alkenyl triflates.

Ref. 250

Carbonylation reactions can be carried out with a boronic acid as the nucleophilic component.²⁵¹

Application of the carbonylation reaction to halides with appropriately placed hydroxy groups leads to lactone formation. In this case the acylpalladium intermediate is trapped intramolecularly.

Ref. 252

Carbonylation can also be carried out as a tandem reaction in intramolecular Heck reactions.

It can also be done by in situ generation of other types of electrophiles. For example, good yields of *N*-acyl α -amino acids are formed in a process in which an amide and aldehyde combine to generate a carbinolamide and, presumably, an acyliminium ion. The organopalladium intermediate is then carbonylated prior to reaction with water.²⁵⁴

Scheme 8.15 gives some examples of carbonylations and acylations involving stannane reagents. Entry 1 illustrates synthesis of diaryl ketones from aryl halides and arylboronic acids. Entries 2 and 3 use stannanes as the nucleophilic reactant. Entry 4 was carried out as part of the synthesis of the *Strychnos* alkaloid akuammicine. The triazinone ring serves to protect the aromatic amino group. Entries 5 and 6 introduce carboxy groups using vinyl and aryl triflates, respectively. Entries 8 and 9 are similar reactions carried out during the course of multistage syntheses. Entry 10 illustrates direct formation of an amide by carbonylation.

8.3. Reactions Involving Other Transition Metals

8.3.1. Organonickel Compounds

The early synthetic processes using organonickel compounds involved the coupling of allylic halides, which react with nickel carbonyl, $\text{Ni}(\text{CO})_4$, to give π -allyl complexes. These complexes react with a variety of halides to give coupling products.²⁵⁵

²⁵⁵ M. F. Semmelhack, *Org. React.*, **19**, 115 (1972).

Nickel carbonyl effects coupling of allylic halides when the reaction is carried out in very polar solvents such as DMF or DMSO. This coupling reaction has been used intramolecularly to bring about cyclization of *bis*-allylic halides and was found useful in the preparation of large rings.

Nickel carbonyl is an extremely toxic substance, but a number of other nickel reagents with generally similar reactivity can be used in its place. The Ni(0) complex of 1,5-cyclooctadiene, Ni(COD)₂, can effect coupling of allylic, alkenyl, and aryl halides.

Tetrakis-(triphenylphosphine)nickel(0) is an effective reagent for coupling aryl halides,²⁶¹ and medium rings can be formed in intramolecular reactions.

Ref. 262

The homocoupling of aryl halides and triflates can be made catalytic in nickel by using zinc as a reductant for in situ regeneration of the active Ni(0) species.

Ref. 263

Ref. 265

Mechanistic study of the aryl couplings has revealed the importance of the changes in redox state that are involved in the reaction.²⁶⁵ Ni(I) , Ni(II) , and Ni(III) states are believed to be involved. Changes in the degree of coordination by phosphine ligands are also thought to be involved, but these have been omitted in the mechanism shown here. The detailed kinetics of the reaction are inconsistent with a mechanism involving only formation and decomposition of a biarylnickel(II) intermediate. The key aspects of the mechanism are: (1) the oxidative addition involving a Ni(I) species, and (2) the reductive elimination that occurs via a diaryl Ni(III) intermediate and regenerates Ni(I) .

Nickel(II) salts are able to catalyze the coupling of Grignard reagents with alkenyl and aryl halides. A soluble *bis*-phosphine complex, $\text{Ni(dppe)}_2\text{Cl}_2$, is a particularly effective catalyst.²⁶⁶ The main distinction between this reaction and Pd-catalyzed cross

coupling is that the nickel reaction can be more readily extended to saturated alkyl groups because of a reduced tendency toward β -elimination.

The reaction has been applied to the synthesis of cyclophane-type structures by use of dihaloarenes and Grignard reagents from α , ω -dihalides.

Ref. 267

Recent discoveries have expanded the utility of nickel-catalyzed coupling reactions. Inclusion of butadiene greatly improves the efficiency of the reactions.²⁶⁸

These reaction conditions are applicable to primary chlorides, bromides, and tosylates. The active catalytic species appears to be a *bis*- π -allyl complex formed by dimerization of butadiene.

A preparation of Ni(II) on charcoal can also be used as the catalyst. It serves as a reservoir of active Ni(0) formed by reduction by the Grignard reagent.²⁶⁹

Aryl carbamates are also reactive toward nickel-catalyzed coupling.²⁷⁰ Since the carbamates can be readily prepared from phenols, they are convenient starting materials.

²⁷⁰. S. Sengupta, M. Leite, D. S. Raslan, C. Quesnelle, and V. Snieckus, *J. Org. Chem.*, **57**, 4066 (1992).

Vinyl carbamates are also reactive.

Ref. 272

Similarly, nickel catalysis permits the extension of cross coupling to vinyl phosphates, which are in some cases more readily obtained and handled than vinyl triflates.²⁷³

Nickel acetylacetonate, $\text{Ni}(\text{acac})_2$, in the presence of a styrene derivative promotes coupling of primary alkyl iodides with organozinc reagents. The added styrene serves to stabilize the active catalytic species, and of the derivatives examined, *m*-trifluoromethylstyrene was the best.²⁷⁴

This method can extend Ni-catalyzed cross coupling to functionalized organometallic reagents.

Nickel can also be used in place of Pd in Suzuki-type couplings of boronic acids. The main advantage of nickel in this application is that it reacts more readily with aryl chlorides²⁷⁵ and methanesulfonates²⁷⁶ than do the Pd systems. These reactants may be more economical than iodides or triflates in large-scale syntheses.

$\text{NiCl}_2[\text{P}(\text{c}\text{-C}_6\text{H}_{11})_3]_2$ is an effective catalyst for coupling aryl tosylates with arylboronic acids.²⁷⁷

Nickel catalysis has been used in a sequential synthesis of terphenyls, starting with 2-, 3-, or 4-bromophenyl neopentanesulfonates. Conventional Pd-catalyzed Suzuki conditions were used for the first step involving coupling of the bromide and then nickel catalysis was utilized for coupling the sulfonate.

Ref. 278

These coupling reactions can also be done with boronate esters activated by conversion to “ate” reagents by reaction with alkyllithium compounds.²⁷⁹ For example, analogs of leukotrienes have been synthesized in this way.

Ref. 280

8.3.2. Reactions Involving Rhodium and Cobalt

Rhodium and cobalt participate in several reactions that are of value in organic syntheses. Rhodium and cobalt are active catalysts for the reaction of alkenes with hydrogen and carbon monoxide to give aldehydes, known as *hydroformylation*.²⁸¹

Ref. 282

100% yield,
3.2:1 ratio

Ref. 283

The key steps in the reaction are addition of hydridorhodium to the double bond of the alkene and migration of the alkyl group to the complexed carbon monoxide. Hydrogenolysis then leads to the aldehyde.

Carbonylation can also be carried out under conditions in which the acylrhodium intermediate is trapped by internal nucleophiles.

80% yield,
70:30 ratio

Ref. 284

The steps in the hydroformylation reaction are closely related to those that occur in the *Fischer-Tropsch process*, which is the reductive conversion of carbon monoxide to alkanes and occurs by a repetitive series of carbonylation, migration, and reduction steps that can build up a hydrocarbon chain.

The Fischer-Tropsch process is of considerable economic interest because it is the basis of conversion of carbon monoxide to synthetic hydrocarbon fuels, and extensive work has been done on optimization of catalyst systems.

The carbonylation step that is involved in both hydroformylation and the Fischer-Tropsch reaction can be reversible. Under appropriate conditions, rhodium catalyst can be used for the decarbonylation of aldehydes²⁸⁵ and acyl chlorides.²⁸⁶

²⁸⁶. J. K. Stille and M. T. Regan, *J. Am. Chem. Soc.*, **96**, 1508 (1974); J. K. Stille and R. W. Fries, *J. Am. Chem. Soc.*, **96**, 1514 (1974).

An acylrhodium intermediate is involved in both cases. The elimination of the hydrocarbon or halide occurs by reductive elimination.²⁸⁷

Although the very early studies of transition metal-catalyzed coupling of organometallic reagents included cobalt salts, the use of cobalt for synthetic purposes is quite limited. Vinyl bromide and iodides couple with Grignard reagents in good yield, but a good donor ligand such as NMP or DMPU is required as a cocatalyst.

Ref. 288

Co(acac)_2 also catalyzes cross coupling of organozinc reagents under these conditions.²⁸⁹

8.4. The Olefin Metathesis Reaction

Several transition metal complexes can catalyze the exchange of partners of two double bonds. Known as the *olefin metathesis reaction*, this process can be used to close or open rings, as well to interchange double-bond components.

Various heterocyclic rings can be closed, as in the formation of an α,β -lactone ring in the synthesis of peloruside A (see also Entries 3 and 5 of Scheme 8.16).

Some of the most impressive successes have come in the synthesis of large rings. Several research groups employed the ring-closing metathesis reaction in the synthesis of epothilone and analogs (see Entry 8 of Scheme 8.14).²⁹⁷ A large ring incorporating a tetrasaccharide unit was synthesized in essentially quantitative yield using either catalyst **F** or **G**. The newly formed double bond is 9:1 *E:Z*.

Olefin metathesis can also be used in intermolecular reactions.²⁹⁹ For example, a variety of functionally substituted side chains were introduced by exchange with the terminal double bond in **5**.³⁰⁰ These reactions gave *E:Z* mixtures.

The effectiveness of these intermolecular reactions depends on the relative reactivity of the two components, since self-metathesis leading to dimeric products will occur if one compound is more reactive than the other.

Triple bonds can also participate in the metathesis reaction. Intramolecular reactions give vinylcycloalkenes, whereas intermolecular reactions provide conjugated dienes.³⁰¹ The mechanism is similar to that for α, ω -diene metathesis, but in contrast to diene cyclization, no carbon atoms are lost.³⁰²

The reaction has been applied in several synthetic contexts. The intermolecular reaction has been used to construct the conjugated diene side chain of mycothiazole, an antibiotic isolated from a sponge.

Ref. 303

The intermolecular version has been used in alkaloid synthesis.

Ref. 304

When the intramolecular version is applied to silyloxyalkynes, the ultimate products are acetyl cycloalkenes.³⁰⁵

This reaction was used to prepare an intermediate suitable for synthesis of the sesquiterpenes α - and β -eremophilane and related structures.³⁰⁶

Diynes can be employed in intramolecular ring-closing metathesis. Several catalysts involving Mo and W have been investigated. These cyclizations can be combined with semihydrogenation to give macrocycles with *Z*-double bonds.

Ref. 307

Ref. 308

Scheme 8.16 gives some examples of the synthetic application of the olefin metathesis reaction. Entry 1 is the synthesis of a structure related to a flour beetle aggregation pheromone. Entry 2 was used in the synthesis of a component of sandalwood oil. These two examples illustrate use of the ring-closing metathesis in the synthesis of common rings. Entry 3 forms an α, β -unsaturated lactone and was used in the synthesis of fostriecin, which has anticancer activity. Entry 4 forms a cyclohexenone. Generally, alkenes with EWG substituents have somewhat reduced reactivity and in this case a mild Lewis acid cocatalyst was required. Entry 5 illustrates the synthesis of a medium-sized ring. In this case, catalyst **G** showed a preference for the *E*-double bond but a catalyst similar to **H** formed the *Z*-isomer. This difference was attributed to more rapid reversibility and thermodynamic control in the latter case. Entry 6 also shows the formation of a medium-size ring. Entries 7 and 8 illustrate the application of the ring-closing metathesis to large rings, with Entry 8 being an example of the synthesis of epothilone by this method.

8.5. Organometallic Compounds with π -Bonding

The organometallic reactions discussed in the previous sections in most cases involved intermediates carbon-metal with σ bonds, although examples of π bonding with alkenes and allyl groups were also encountered. The reactions emphasized in this section involve compounds in which organic groups are bound to the metal through delocalized π systems. Among the classes of organic compounds that can serve as π ligands are alkenes, allyl groups, dienes, the cyclopentadienide anion, and aromatic compounds. There are many such compounds, and we illustrate only a few examples. The bonding of polyenes in π complexes is the result of two major contributions. The filled π orbital acts as an electron donor to empty d orbitals of the metal ion. There is also a contribution to bonding, called “back bonding,” from a filled metal orbital interacting with ligand π^* orbitals. These two types of bonding are illustrated in Figure 8.6. These same general bonding concepts apply to all the other π organometallics. The details of structure and reactivity of the individual compound depend on such factors as: (a) the number of electrons that can be accommodated by the metal; (b) the oxidation level of the metal; and (c) the electronic character of other ligands on the metal.

Alkene-metal complexes are usually prepared by a process by which some other ligand is dissociated from the metal. Both thermal and photochemical reactions are used.

Ref. 309

Ref. 310

π -Allyl complexes of palladium were described in Section 8.2.1. Similar π -allyl complexes of nickel can be prepared either by oxidative addition on Ni(0) or by transmetalation of a Ni(II) salt. Some reactions of these allyl nickel species are discussed in Section 8.3.1.

Ref. 311

Ref. 312

Organic ligands having a cyclic array of four carbon atoms have been of particular interest in connection with the chemistry of cyclobutadiene. Organometallic compounds containing cyclobutadiene as a ligand were first prepared in 1965.³¹³ The carbocyclic ring in the cyclobutadiene–iron tricarbonyl complex reacts as an aromatic ring and can undergo electrophilic substitutions.³¹⁴ Subsequent studies showed that oxidative decomposition of the complex can liberate cyclobutadiene, which is trapped by appropriate reactants.³¹⁵ Some examples of these reactions are given in Scheme 8.17.

One of the most familiar of the π -organometallic compounds is ferrocene, a neutral compound that is readily prepared from cyclopentadienide anion and iron(II).³¹⁶

Numerous chemical reactions have been carried out on ferrocene and its derivatives.³¹⁷ The molecule behaves as an electron-rich aromatic system, and electrophilic substitution reactions occur readily. Reagents that are relatively strong oxidizing agents, such as the halogens, effect oxidation at iron and destroy the compound.

c. L. Watts, J. D. Fitzpatrick, and R. Pettit, *J. Am. Chem. Soc.*, **88**, 623 (1966).

d. P. Reeves, J. Henery, and R. Pettit, *J. Am. Chem. Soc.*, **91**, 3889 (1969).

Many other π -organometallic compounds have been prepared. In the most stable of these, the total number of electrons contributed by the ligands (e.g., four for allyl anions and six for cyclopentadiene anion) plus the valence electrons on the metal atom or ion is usually 18, to satisfy the *effective atomic number rule*.³¹⁸

One of the most useful types of π complexes of aromatic compounds from the synthetic point of view are chromium tricarbonyl complexes obtained by heating benzene or other aromatics with Cr(CO)_6 .

Norton, and R. G. Finke, *Principles and Applications of Organotransition Metal Chemistry*, University Science Books, Mill Valley, CA, 1987, pp. 166–173.

³¹⁹. W. Strohmeier, *Chem. Ber.*, **94**, 2490 (1961).

Ref. 320

The Cr(CO)_3 unit in these compounds is strongly electron withdrawing and activates the ring to nucleophilic attack. Reactions with certain carbanions results in arylation.³²¹

In compounds in which the aromatic ring does not have a leaving group, addition occurs. The intermediate can be oxidized by I_2 .

Ref. 322

Existing substituent groups such as CH_3 , OCH_3 , and $^+\text{N}(\text{CH}_3)_3$ exert a directive effect, often resulting in a major amount of the *meta* substitution product.³²³ The intermediate adducts can be converted to cyclohexadiene derivatives if the adduct is protonolyzed.³²⁴

Not all carbon nucleophiles will add to arene chromium tricarbonyl complexes. For example, alkyl lithium reagents and simple ketone enolates do not give adducts.³²⁵

Organometallic chemistry is a very large and active field of research and new compounds, reactions, and useful catalysts are being discovered at a rapid rate. These developments have had a major impact on organic synthesis and future developments can be expected.

8.5. Vinyltriphenylphosphonium ion has been found to react with cuprate reagents by nucleophilic addition, generating an ylide that can react with aldehydes to give alkenes. In another version of the reaction, an intermediate formed by the reaction of the cuprate with acetylene adds to vinyltriphenylphosphonium ion to generate an ylide intermediate. Show how these reactions can be used to prepare the following products from the specified starting materials.

8.6. It has been observed that the reaction of $[(\text{C}_2\text{H}_5)_2\text{Cu}]\text{Li}$ or $[(\text{C}_2\text{H}_5)_2\text{CuCNLi}_2]$ with 2-iodooctane proceeds with racemization in both cases. On the other hand, the corresponding bromide reacts with nearly complete inversion of configuration with both reagents. When 6-halo-2-heptenes are used in similar reactions with $[(\text{CH}_3)_2\text{Cu}]\text{Li}$, the iodide gives a cyclic product 1-ethyl-2-methylcyclopentane, whereas the bromide gives mainly 6-methyl-1-heptene. Propose a mechanism that accounts for the different behavior of the iodides as compared to the bromides.

8.7. Short synthetic sequences involving no more than three steps can be used to prepare the compound shown on the left from the potential starting materials on the right. Suggest an appropriate series of reactions involving one or more organometallic reagent for each transformation.

8.8. The conversions shown below can be carried out in multistep, but one-pot, reactions in which none of the intermediates needs to be isolated. Show how you would perform the transformations by suggesting a sequence of reagents and the approximate reaction conditions.

8.9. A number of syntheses of medium- and large-ring compounds that involve transition metal reagents or catalysts have been described. Suggest an organometallic reagent or catalyst that could bring about each of the following transformations.

- 8.10. The cyclobutadiene complex **10-A** can be prepared in enantiomerically pure form. When the complex is decomposed by an oxidizing reagent in the presence of a potential trapping agent, the products are racemic. When the reaction is carried out only to partial completion, the unreacted complex remains enantiomerically pure. Discuss the relevance of these results to the following question: "In oxidative decomposition of cyclobutadiene-iron tricarbonyl complexes, is the cyclobutadiene released from the complex before or after it has reacted with the trapping reagent?"

- 8.11. When the isomeric allylic acetates **11-A** and **11-B** react with dialkylcuprates, they give very similar product mixtures that contain mainly **11-C** with a small amount of **11-D**. Discuss the mechanistic implications of the formation of essentially the same product mixture from both reactants.

- 8.12. The compound shown below is a constituent of the pheromone of the codling moth. It has been synthesized using *n*-propyl bromide, propyne, 1-pentyne,

ethylene oxide, and CO_2 as the source of the carbon atoms. Devise a route for such a synthesis. Hint: Extensive use of organocopper reagents is the basis for the synthesis.

- 8.13. (*S*)-3-Hydroxy-2-methylpropanoic acid, **13-A**, can be obtained in enantiomerically pure form from isobutyric acid by a microbiological oxidation. The aldehyde **13-B** is available from a natural product, pulegone, also in enantiomerically pure form. Devise a synthesis of enantiomerically pure **13-C**, a compound of interest as a starting material for the synthesis of α -tocopherol (vitamin E).

- 8.14. Each of the following conjugate additions can be carried out in good yield under optimized conditions. Consider the special factors in each case and suggest a reagent and reaction conditions that would be expected to give good yields.

- 8.15. Each of the following synthetic transformations can be accomplished by use of organometallic reagents and/or catalysts. Indicate a sequence of reactions that will permit each of the syntheses to be completed.

8.16. Each of the following reactions can be accomplished with a palladium reagent or catalyst. Write a detailed mechanism for each reaction. The number of equivalents of each reagent is given in parentheses. Specify the oxidation state of Pd in the intermediates. Be sure your mechanism accounts for the regeneration of catalytically active species in those reactions that are catalytic in palladium.

8.17. The reaction of lithium dimethylcuprate with **17-A** shows considerable 1,4-diastereoselectivity. Offer an explanation, including a transition structure.

8.18. The following transformations have been carried out to yield a specific enantiomer using organometallic reagents. Devise a strategy by which organometallic reagents or catalysts can be used to prepare the desired compound from the specified starting material.

- 8.19. Under the conditions of the Wacker oxidation, 4-trimethylsilyl-3-alkyn-1-ols give γ -lactones. Similarly, *N*-carbamoyl or *N*-acetyl 4-trimethylsilyl-3-alkynamines cyclize to γ -lactams. Formulate a mechanism for these reactions. (Hint: In D_2O , the reaction gives 3,3-dideuterated products.)

- 8.20. The tricyclic compound **20-C**, a potential intermediate for alkaloid synthesis, has been prepared by an intramolecular Diels-Alder reaction of the ketone obtained by deprotection and oxidation of **20-B**. Compound **20-B** was prepared from **20-A** using alkyne-ethene metathesis chemistry. Show the mechanistic steps involved in conversion of **20-A** to **20-B**.

Carbon-Carbon Bond-Forming Reactions of Compounds of Boron, Silicon, and Tin

Introduction

In this chapter we discuss the use of boron, silicon, and tin compounds to form carbon-carbon bonds. These elements are at the metal-nonmetal boundary, with boron being the most and tin the least electronegative of the three. The neutral alkyl derivatives of boron have the formula R_3B , whereas silicon and tin are tetravalent compounds, R_4Si and R_4Sn . These compounds are relatively volatile nonpolar substances that exist as discrete molecules and in which the carbon-metal bonds are largely covalent. By virtue of the electron deficiency at boron, the boranes are Lewis acids. Silanes do not have strong Lewis acid character but can form pentavalent adducts with hard bases such as alkoxides and especially fluoride. Silanes with halogen or sulfonate substituents are electrophilic and readily undergo nucleophilic displacement. Stannanes have the potential to act as Lewis acids when substituted by electronegative groups such as halogens. Either displacement of a halide or expansion to pentacoordinate or hexacoordinate structures is possible.

In contrast to the transition metals, where there is often a change in oxidation level at the metal during the reaction, there is usually no change in oxidation level for boron, silicon, and tin compounds. The synthetically important reactions of these three groups of compounds involve transfer of a carbon substituent with one (radical equivalent) or two (carbanion equivalent) electrons to a reactive carbon center. Here we focus on the nonradical reactions and deal with radical reactions in Chapter 10. We have already introduced one important aspect of boron and tin chemistry in the transmetallation reactions involved in Pd-catalyzed cross-coupling reactions, discussed

in Section 8.2.3. This chapter emphasizes the use of boranes, silanes, and stannanes as sources of nucleophilic carbon groups toward a variety of electrophiles, especially carbonyl compounds.

Allylic derivatives are particularly important in the case of boranes, silanes, and stannanes. Allylic boranes effect nucleophilic addition to carbonyl groups via a cyclic TS that involves the Lewis acid character of the borane. 1,3-Allylic transposition occurs through the cyclic TS.

Allylic silanes and stannanes react with various electrophiles with demetallation. These reactions can occur via several related mechanisms. Both types of reactants can deliver allylic groups to electrophilic centers such as carbonyl and iminium.

Alkenyl silanes and stannanes have the potential for nucleophilic delivery of vinyl groups to a variety of electrophiles. Demetallation also occurs in these reactions, so the net effect is substitution for the silyl or the stannyl group.

9.1. Organoboron Compounds

9.1.1. Synthesis of Organoboranes

The most widely used route to organoboranes is hydroboration, introduced in Section 4.5.1, which provides access to both alkyl- and alkenylboranes. Aryl-, methyl-, allylic, and benzylboranes cannot be prepared by hydroboration, and the most general route to these organoboranes is by reaction of an organometallic compound with a halo- or alkoxyboron derivative.¹

¹. H. C. Brown and P. K. Jadhar, *J. Am. Chem. Soc.*, **105**, 2092 (1983).

Alkyl, aryl, and allyl derivatives of boron can be prepared directly from the corresponding halides, BF_3 , and magnesium metal. This process presumably involves in situ generation of a Grignard reagent, which then displaces fluoride from boron.²

Alkoxy groups can be displaced from boron by alkyl- or aryllithium reagents. The reaction of diisopropoxy boranes with an organolithium reagent, for example, provides good yields of unsymmetrically disubstituted isopropoxyboranes.³

Organoboranes can also be made using organocopper reagents. One route to methyl and aryl derivatives is by reaction of a dialkylborane, such as 9-BBN, with a cuprate reagent.⁴

These reactions occur by oxidative addition at copper, followed by decomposition of the Cu(III) intermediate.

Two successive reactions with different organocuprates can convert thexylborane to an unsymmetrical trialkylborane.⁵

In addition to trialkylboranes, various alkoxyboron compounds have prominent roles in synthesis. Some of these, such as catecholboranes (see. p. 340) can be made by hydroboration. Others are made by organometallic or related substitution reactions. Alkoxyboron compounds are usually named as esters. Compounds with one alkoxy group are esters of borinic acids and are called *borinates*. Compounds with two alkoxy groups are called *boronates*. Trialkoxyboron compounds are *borates*.

R_2BOH	$\text{R}_2\text{BOR}'$	RB(OH)_2	RB(OR')_2	B(OH)_3	B(OR')_3

The cyclic five- and six-membered boronate esters are used frequently. Their systematic names are 1,3,2-dioxaborolane and 1,3,2-dioxaborinane, respectively.

1,3,2-dioxaborolane

1,3,2-dioxaborinane

9.1.2. Carbonylation and Other One-Carbon Homologation Reactions

The reactions of organoboranes that we discussed in Chapter 4 are valuable methods for introducing functional groups such as hydroxy, amino, and halogen into alkenes. In this section we consider carbon-carbon bond-forming reactions of boron compounds.⁶ Trivalent organoboranes are not very nucleophilic but they are moderately reactive Lewis acids. Most reactions in which carbon-carbon bonds are formed involve a tetracoordinate intermediate that has a negative charge on boron. Adduct formation weakens the boron-carbon bonds and permits a transfer of a carbon substituent with its electrons. The general mechanistic pattern is shown below.

The electrophilic center is sometimes generated from the Lewis base by formation of the adduct, and the reaction proceeds by migration of a boron substituent.

A significant group of reactions of this type involves the reactions of organoboranes with carbon monoxide, which forms Lewis acid-base complexes with the organoboranes. In these adducts the boron bears a formal negative charge and carbon is electrophilic because the triple bond to the oxygen bears a formal positive charge. The adducts undergo boron to carbon migration of the alkyl groups. The reaction can be controlled so that it results in the migration of one, two, or all three of the boron substituents.⁷ If the organoborane is heated with carbon monoxide to 100°–125 °C, all of the groups migrate and a tertiary alcohol is obtained after workup by oxidation. The presence of water causes the reaction to cease after migration of two groups from boron to carbon. Oxidation of the reaction mixture at this stage gives a ketone.⁸ Primary alcohols are obtained when the carbonylation is carried out in the presence of

⁶. For a review of this topic, see E. Negishi and M. Idacavage, *Org. React.*, **33**, 1 (1985).

⁷. H. C. Brown and M. W. Rathke, *J. Am. Chem. Soc.*, **89**, 2737 (1967).

⁸. H. C. Brown and M. W. Rathke, *J. Am. Chem. Soc.*, **89**, 2738 (1967).

sodium borohydride or lithium borohydride.⁹ The product of the first migration step is reduced and subsequent hydrolysis gives a primary alcohol.

In this synthesis of primary alcohols, only one of the three groups in the organoborane is converted to product. This disadvantage can be overcome by using a dialkylborane, particularly 9-BBN, in the initial hydroboration. (See p. 338 to review the abbreviations of some of the common boranes.) After carbonylation and B \rightarrow C migration, the reaction mixture can be processed to give an aldehyde, an alcohol, or the homologated 9-alkyl-BBN.¹⁰ The utility of 9-BBN in these procedures is the result of the minimal tendency of the bicyclic ring to undergo migration.

Several alternative procedures have been developed in which other reagents replace carbon monoxide as the migration terminus.¹¹ The most generally applicable of these methods involves the use of cyanide ion and trifluoroacetic anhydride (TFAA). In this reaction the borane initially forms an adduct with cyanide ion. The migration is induced by N-acylation of the cyano group by TFAA. Oxidation and hydrolysis then give a ketone.

¹⁰ H. C. Brown, E. F. Knights, and R. A. Coleman, *J. Am. Chem. Soc.*, **91**, 2144 (1969); H. C. Brown, T. M. Ford, and J. L. Hubbard, *J. Org. Chem.*, **45**, 4067 (1980).

¹¹ H. C. Brown and S. M. Singh, *Organometallics*, **5**, 998 (1986).

Another useful reagent for introduction of the carbonyl carbon is dichloromethyl methyl ether. In the presence of a hindered alkoxide base, it is deprotonated and acts as a nucleophile toward boron. Rearrangement then ensues with migration of two boron substituents. Oxidation gives a ketone.

Unsymmetrical ketones can be made by using either thexylborane or thexylchloroborane.¹² Thexylborane works well when one of the desired carbonyl substituents is derived from a moderately hindered alkene. Under these circumstances, a clean monoalkylation of thexylborane can be accomplished, which is then followed by reaction with a second alkene and carbonylation.

Thexylchloroborane can be alkylated and then converted to a dialkylborane by a reducing agent such as $\text{KBH}[\text{OCH}(\text{CH}_3)_2]_3$, an approach that is preferred for terminal alkenes.

The success of both of these methods depends upon the thexyl group being noncompetitive with the other groups in the migration steps.

The formation of unsymmetrical ketones can also be done starting with IpcBCl_2 . Sequential reduction and hydroboration are carried out with two different alkenes. The first reduction can be done with $(\text{CH}_3)_3\text{SiH}$, but the second stage requires LiAlH_4 .

As can be judged from the preceding discussion, organoboranes are versatile intermediates for formation of carbon-carbon bonds. An important aspect of all of these synthetic procedures involving boron to carbon migration is that they occur with *retention of the configuration of the migrating group*. Since effective procedures for enantioselective hydroboration have been developed (see Section 4.5.3), these reactions offer the opportunity for enantioselective synthesis. A sequence for enantioselective formation of ketones starts with hydroboration by mono(isopinocampheyl)borane, (IpcBH₂), which can be obtained in high enantiomeric purity.¹⁶ The hydroboration of a prochiral alkene establishes a new stereocenter. A third alkyl group can be introduced by a second hydroboration step.

The trialkylborane can be transformed to a dialkyl(ethoxy)borane by heating with acetaldehyde, which releases the original chiral α -pinene. Finally application of one of the carbonylation procedures outlined in Scheme 9.1 gives a chiral ketone.¹⁷ The enantiomeric excess observed for ketones prepared in this way ranges from 60–90%.

¹⁶. H. C. Brown, P. K. Jadhav, and A. K. Mandal, *J. Org. Chem.*, **47**, 5074 (1982).

¹⁷. H. C. Brown, R. K. Jadhav, and M. C. Desai, *Tetrahedron*, **40**, 1325 (1984).

Higher enantiomeric purity can be obtained by a modified procedure in which the monoalkylborane intermediate is prepared by reduction of a cyclic boronate.¹⁸

Subsequent steps involve introduction of a hexyl group and then the second ketone substituent. Finally, the ketone is formed by the cyanide-TFAA method.

By starting with enantiomerically enriched IpcBHCl, it is possible to construct chiral cyclic ketones. For example, stepwise hydroboration of 1-allylcyclohexene and ring construction provides *trans*-1-decalone in greater than 99% e.e.¹⁹

9.1.3. Homologation via α -Haloenolates

Organoboranes can also be used to construct carbon-carbon bonds by several other types of reactions that involve migration of a boron substituent to carbon. One such reaction involves α -halo carbonyl compounds.²⁰ For example, ethyl bromoacetate reacts with trialkylboranes in the presence of base to give alkylated acetic acid derivatives in excellent yield. The reaction is most efficiently carried out with a 9-BBN derivative. These reactions can also be effected with β -alkenyl derivatives of 9-BBN to give β,γ -unsaturated esters.²¹

²⁰. H. C. Brown, M. M. Rogic, M. W. Rathke, and G. W. Kabalka, *J. Am. Chem. Soc.*, **90**, 818 (1968); H. C. Brown and M. M. Rogic, *J. Am. Chem. Soc.*, **91**, 2146 (1969).

²¹. H. C. Brown, N. G. Bhat, and J. B. Cambell, Jr., *J. Org. Chem.*, **51**, 3398 (1986).

The reactions can be made enantioselective by using enantiomerically pure IpcBH_2 for hydroboration of alkenes and then transforming the products to enantiomerically pure derivatives of 9-BBN by reaction with 1,5-cyclooctadiene.²²

The mechanism of these alkylations involves a tetracoordinate boron intermediate formed by addition of the enolate of the α -bromo ester to the organoborane. The migration then occurs with displacement of bromide ion. In agreement with this mechanism, retention of configuration of the migrating group is observed.²³

α -Halo ketones and α -halo nitriles undergo similar reactions.²⁴

A closely related reaction employs α -diazo esters or α -diazo ketones.²⁵ With these compounds, molecular nitrogen acts as the leaving group in the migration step. The best results are achieved using dialkylchloroboranes or monoalkyldichloroboranes.

A number of these alkylation reactions are illustrated in Scheme 9.2. Entries 1 and 2 are typical examples of α -halo ester reactions. Entry 3 is a modification in which the highly hindered base potassium 2,6-di-*t*-butylphenoxide is used. Similar reaction conditions can be used with α -halo ketones (Entries 4 and 5) and nitriles (Entry 6). Entries 7 to 9 illustrate the use of diazo esters and diazo ketones. Entry 10 shows an application of the reaction to the synthesis of an amide.

9.1.4. Stereoselective Alkene Synthesis

Several methods for stereoselective alkene synthesis are based on boron intermediates. One approach involves alkenylboranes, which can be prepared from terminal alkynes. Procedures have been developed for the synthesis of both *Z*- and *E*-alkenes.

Treatment of alkenyldialkylboranes with iodine results in the formation of the *Z*-alkene with migration of one boron substituent.²⁶

Similarly, alkenyllithium reagents add to dimethyl boronate to give adducts that decompose to *Z*-alkenes on treatment with iodine.²⁷

The synthesis of *Z*-alkenes can also be carried out starting with an alkylbromoborane, in which case migration presumably follows replacement of the bromide by methoxide.²⁸

The stereoselectivity of these reactions arises from a base-induced *anti* elimination after the migration. The elimination is induced by addition of methoxide to the boron, generating an anionic center.

E-Alkenes can be prepared by several related reactions.²⁹ Hydroboration of a bromoalkyne generates an α -bromoalkenylborane. On treatment with methoxide ion these intermediates undergo B \rightarrow C migration to give an alkyl alkenylborinate. Protonolysis generates an *E*-alkene.

The dialkylboranes can be prepared from hexylchloroborane. The hexyl group does not normally migrate.

A similar strategy involves initial hydroboration by BrBH_2 .³⁰

Stereoselective syntheses of trisubstituted alkenes are based on *E*- and *Z*-alkenyldioxaborinanes. Reaction with an alkyl lithium reagent forms an “ate” adduct that rearranges on treatment with iodine in methanol.³¹

Both alkynes and alkenes can be obtained from adducts of terminal alkynes and boranes. Reaction with iodine induces migration and results in the formation of the alkylated alkyne.³²

The mechanism involves electrophilic attack by iodine at the triple bond, which induces migration of an alkyl group from boron. This is followed by elimination of dialkyliodoboron.

If the alkyne is hydroborated and then protonolyzed a *Z*-alkene is formed. This method was used to prepare an insect pheromone containing a *Z*-double bond.

Ref. 33

The $\text{B} \rightarrow \text{C}$ migration can also be induced by other types of electrophiles. Trimethylsilyl chloride or trimethylsilyl triflate induces a stereospecific migration to form β -trimethylsilyl alkenylboranes having *cis* silicon and boron substituents.³⁴ It has been suggested that this stereospecificity arises from a silicon-bridged intermediate.

Tributyltin chloride also induces migration and gives the product in which the $\text{C}-\text{Sn}$ bond is *cis* to the $\text{C}-\text{B}$ bond. Protonolysis of both the $\text{C}-\text{Sn}$ and $\text{C}-\text{B}$ bonds by acetic acid gives the corresponding *Z*-alkene.³⁵

9.1.5. Nucleophilic Addition of Allylic Groups from Boron Compounds

Allylic boranes such as 9-allyl-9-BBN react with aldehydes and ketones to give allylic carbinols. The reaction begins by Lewis acid-base coordination at the carbonyl oxygen, which both increases the electrophilicity of the carbonyl group and weakens the $\text{C}-\text{B}$ bond to the allyl group. The dipolar adduct then reacts through a cyclic TS. Bond formation takes place at the γ -carbon of the allyl group and the double bond shifts.³⁶ After the reaction is complete, the carbinol product is liberated from the borinate ester by displacement with ethanolamine. Yields for a series of aldehydes and ketones were usually above 90% for 9-allyl-9-BBN.

The cyclic mechanism predicts that the addition reaction will be stereospecific with respect to the geometry of the double bond in the allylic group, and this has been demonstrated to be the case. The *E*- and *Z*-2-butenyl cyclic boronates **1** and **2** were synthesized and allowed to react with aldehydes. The *E*-boronate gave the carbinol with *anti* stereochemistry, whereas the *Z*-boronate resulted in the *syn* product.³⁷

This stereochemistry is that predicted by a cyclic TS in which the aldehyde substituent occupies an equatorial position.

The diastereoselectivity observed in simple systems led to investigation of enantiomerically pure aldehydes. It was found that the *E*- and *Z*-2-butenylboronates both exhibit high *syn-anti* diastereoselectivity with chiral α -substituted aldehydes. However, only the *Z*-isomer also exhibited high selectivity toward the diastereotopic faces of the aldehyde.³⁸

The allylation reaction has been extended to enantiomerically pure allylic boranes and borinates. For example, the 3-methyl-2-butenyl derivative of $(Ipc)_2BH$ reacts with aldehydes to give carbinols of greater than 90% e.e. in most cases.³⁹

³⁷ R. W. Hoffmann and H.-J. Zeiss, *J. Org. Chem.*, **46**, 1309 (1981); K. Fujita and M. Schlosser, *Helv. Chim. Acta*, **65**, 1258 (1982).

β -Allyl-*bis*-(isopinocampheyl)borane exhibits high stereoselectivity in reactions with chiral α -substituted aldehydes.⁴⁰ The stereoselectivity is *reagent controlled*, in that there is no change in stereoselectivity between the two enantiomeric boranes in reaction with a chiral aldehyde. Rather, the configuration of the product is determined by the borane. Both enantiomers of $(\text{Ipc})_2\text{BH}$ are available, so either enantiomer can be prepared from a given aldehyde.

It has been found that conditions in which purified allylic boranes are used give even higher enantioselectivity and faster reactions than the reagents prepared and used *in situ*. The boranes are prepared from Grignard reagents and evidently the residual Mg^{2+} salts inhibit the addition reaction. Magnesium-free borane solutions can be obtained by precipitation and extracting the borane into pentane. These purified reagents react essentially instantaneously with typical aldehydes at -100°C .⁴¹

Another extensively developed group of allylic boron reagents for enantioselective synthesis is derived from tartrates.⁴²

⁴⁰ H. C. Brown, K. S. Bhat, and R. S. Randad, *J. Org. Chem.*, **52**, 319 (1987); H. C. Brown, K. S. Bhat, and R. S. Randad, *J. Org. Chem.*, **54**, 1570 (1989).

⁴¹ U. S. Racherla and H. C. Brown, *J. Org. Chem.*, **56**, 401 (1991).

⁴² W. R. Roush, K. Ando, D. B. Powers, R. L. Halterman, and A. Palkowitz, *Tetrahedron Lett.*, **29**, 5579 (1988); W. R. Roush, L. Banfi, J. C. Park, and L. K. Hong, *Tetrahedron Lett.*, **30**, 6457 (1989).

With unhindered aldehydes such as cyclohexanecarboxaldehyde, the diastereoselectivity is higher than 95%, with the *E*-boronate giving the *anti* adduct and the *Z*-boronate giving the *syn* adduct. Enantioselectivity is about 90% for the *E*-boronate and 80% for the *Z*-boronate. With more hindered aldehydes, such as pivaldehyde, the diastereoselectivity is maintained but the enantioselectivity drops somewhat. These reagents also give excellent double stereodifferentiation when used with chiral aldehydes. For example, the aldehydes **3** and **4** give at least 90% enantioselection with both the *E*- and *Z*-boronates.⁴³

These reagents exhibit reagent control of stereoselectivity and have proven to be very useful in stereoselective synthesis of polyketide natural products, which frequently contain arrays of alternating methyl and oxygen substituents.⁴⁴

The enantioselectivity is consistent with cyclic TSs. The key element determining the orientation of the aldehyde within the TS is the interaction of the aldehyde group with the tartrate ligand.

The preferred orientation results from the greater repulsive interaction between the carbonyl groups of the aldehyde and ester in the disfavored orientation.⁴⁵ There is also an attractive electrostatic interaction between the ester carbonyl and the aldehyde

⁴³ W. R. Roush, A. D. Palkowitz, and M. A. J. Palmer, *J. Org. Chem.*, **52**, 316 (1987); W. R. Roush, K. Ando, D. B. Powers, A. D. Palkowitz, and R. L. Halterman, *J. Am. Chem. Soc.*, **112**, 6339 (1990); W. R. Roush, A. D. Palkowitz, and K. Ando, *J. Am. Chem. Soc.*, **112**, 6348 (1990).

carbon.⁴⁶ This orientation and the *E*- or *Z*-configuration of the allylic group as part of a chair TS determine the stereochemistry of the product.

Detailed studies have been carried out on the stereoselectivity of α - and β -substituted aldehydes toward the tartrate boronates.⁴⁷ α -Benzyloxy and β -benzyloxy- α -methylpropionaldehyde gave approximately 4:1 diastereoselectivity with both the *R,R*- and *S,S*- enantiomers. The stereoselectivity is reagent (tartrate) controlled. The acetonide of glyceraldehydes showed higher stereoselectivity.

The tartrate-based allylboration reaction has been studied computationally using B3LYP/6-31G* calculations.⁴⁶ The ester groups were modeled by formyl. It was concluded that the major factor in determining enantioselectivity is a favorable electrostatic interaction between a formyl oxygen lone pair and the positively polarized carbon of the reacting aldehyde. This gives rise to a calculated energy difference of 1.6 kcal/mol between the best *si* and the best *re* TS (see Figure 9.1). In the preferred conformation of the TS, the formyl carbonyl is nearly in the plane of the dioxaborolane ring. This orientation has been calculated to be optimal for α -oxy esters⁴⁸ and is observed in the crystal structure of the tartrate ligands.⁴⁹

Fig. 9.1. Most favorable *si* and *re* transition structures for allylboration of acetaldehyde. The *si* TS is favored by 1.75 kcal/mol, which is attributed to an electrostatic attraction between a formyl carbonyl oxygen lone pair and the acetaldehyde carbonyl carbon. In the *re* TS, there is a repulsive interaction between lone pairs on the formyl and acetaldehyde carbonyl oxygens. Reproduced from *J. Am. Chem. Soc.*, **124**, 10692 (2002), by permission of the American Chemical Society.

Visual models, additional information and exercises on Allylboration can be found in the Digital Resource available at: Springer.com/carey-sundberg.

Another computational study examined the effect that the boron ligands might have on the reactivity of allyl derivatives.⁵⁰ The order found is shown below and is related to the level of the boron LUMO. The dominant factor seems to be the π -donor capacity of the ligands. The calculated order is consistent with experimental data.⁵¹

Recently the scope of the allylboration has been expanded by the discovery that it is catalyzed by certain Lewis acids, especially $\text{Sc}(\text{OTf})_3$.⁵² The catalyzed reaction exhibits the same high diastereoselectivity as the uncatalyzed reaction, which indicates that it proceeds through a cyclic TS.

The catalysis has made reactions of certain functionalized boronates possible. For example, a carbocupration and alkylation allowed the synthesis of boronate **5**. Reaction with aldehydes gave α -methylene lactones with high stereoselectivity.⁵³

The catalysis has been extended for use with chiral boronates and those from the phenyl-substituted bornane diol derivatives **A** and **B**⁵⁴ have been found to be particularly effective.⁵⁵

These reagents have been utilized for allyl-, 2-methylallyl-, and *E*- and *Z*-2-butenyl derivatives. Enantioselectivity of 90–95% is achieved with alkyl- and aryl-, as well as α - and β -siloxy aldehydes.

This method has been applied to the synthesis of (*S*)-2-methyl-4-octanol, an aggregation pheromone of *Metamasius hemipterus*.⁵⁶

Mechanistic studies have suggested that the TS involves bonding of Sc^{3+} to one of the boronate oxygens,⁵⁷ which is consistent with the observation that the catalysts do not have much effect on the rate of allylic boranes. The phenyl substituent on the

boronate is thought to assist in the aldehyde binding through a π - π^* interaction with the aromatic ring.

Various functionalized allylic boronates have been prepared.⁵⁸ Z-3-Methoxy derivatives can be prepared by lithiation of allyl methyl ether and substitution.⁵⁹

They react with aldehydes to give α -methoxy alcohols.

Ref. 60

Oxygenated allylic derivatives of $(\text{Ipc})_2\text{BH}$ also show excellent diastereoselectivity.

1-Methoxy-2-butenyl pinacol boronates show good stereoselectivity toward achiral aldehydes.⁶¹

These reagents were also examined with chiral α -substituted aldehydes. The allylboron reagent dominates the enantioselectivity in both matched and mismatched pairs.

Chloro-substituted $[\text{Ipc}]_2\text{BH}$ derivatives have proven useful for enantioselective synthesis of vinyl epoxides.⁶²

Allyl tetrafluoroborates are also useful allylboration reagents. They can be made from allylic boronic acids and are stable solids.⁶³ The reaction with aldehydes is mediated by BF_3 , which is believed to provide the difluoroborane by removing a fluoride. The addition reactions occur with high stereoselectivity, indicating a cyclic TS.

β -Alkynyl derivatives of 9-BBN act as mild sources of nucleophilic acetylenic groups. Reaction occurs with both aldehydes and ketones, but the rate is at least 100 times faster for aldehydes.⁶⁴

The facility with which the transfer of acetylenic groups occurs is associated with the relative stability of the *sp*-hybridized carbon. This reaction is an alternative to the more common addition of magnesium or lithium salts of acetylides to aldehydes.

Scheme 9.3 illustrates some examples of syntheses of allylic carbinols via allylic boranes and boronate esters. Entries 1 and 2 are among the early examples that

demonstrate the high diastereoselectivity of the allylboration reaction. Entry 3 examines the facial selectivity of glyceraldehyde acetonide toward the achiral reagents derived from butenyl pinacol borane. It was found that the reaction with the *Z*-2-butenyl derivative is highly enantioselective, the *E*-isomer was much less so. It was suggested that steric interaction of the *E*-methyl group with the dioxolane in the expected TS ring led to involvement of a second transition structure.

Entry 4 shows the reaction of 9-(*E*-2-butenyl)-9BBN with methyl pyruvate. This reaction is not very stereoselective, which is presumably due to a modest preference for the orientation of the methyl and methoxycarbonyl groups in the TS. Only use of an extremely sterically demanding pyruvic ester achieved high diastereoselectivity.

R	product ratio	
CH ₃	73	27
Ph	80	20
2,6-diMePh	75	25
2,4,6-tri- <i>t</i> -BuPh	100	0

Entry 5 is an example of use of an α -trimethylsilylallyl group to prepare a vinylsilane. The stereochemistry is consistent with a cyclic TS having the trimethylsilyl substituent in a quasi-axial position to avoid interaction with the bridgehead hydrogen of the bicyclic ring.

Entries 6 and 7 involve functionalized allyl groups, with a *Z*- γ -methoxy group in Entry 6 and a *Z*- γ -chloro group in Entry 7. Both give *syn* products; in the case of Entry 7 the chlorohydrin was cyclized to the *cis* epoxide, which is a pheromone (Iamoxirene) of a species of algae. Entry 8 is another example of the use of a chloro-substituted allylic borane. Entry 9 involves one of the alternatives to $(\text{Ipc})_2\text{BH}$ for enantioselective allylation. In Entry 10, both the aldehyde and allyl group contain chiral centers, but the borane is presumably the controlling factor in the stereoselectivity. Entries 11 to 13 demonstrate several enantioselective reactions using the tartrate-derived chiral auxiliaries. Entry 14 is an example of *reactant-controlled* stereochemistry involving the achiral β -allyl pinacol borane. This reaction proceeded with low stereochemical control to give four isomers in a ratio of 18:3.4:1.4:1. Entry 15 shows high diastereoselectivity and enantioselectivity in a reaction with a *Z*- γ -methoxyallyl- $(\text{Ipc})_2$ -borane. Entries 16 to 19 are examples of the use of allylboration in multistage syntheses. Entry 16 reflects magnesium-free conditions (see p. 799). Entry 17 was used to construct balanol, a PKC inhibitor, and demonstrates *reagent control* of stereochemistry by allyl- $\text{B}(\text{Ipc})_2$ without interference from the protected α -amino and β -hydroxy substituents. Entries 18 and 19 also involve functionalized aldehydes.

9.2. Organosilicon Compounds

9.2.1. Synthesis of Organosilanes

Silicon is similar in electronegativity to carbon. The carbon-silicon bond is quite strong (~ 75 kcal) and trialkylsilyl groups are stable to many of the reaction conditions that are used in organic synthesis. Much of the repertoire of synthetic organic chemistry can be used for elaboration of organosilanes.⁶⁵ For example, the Grignard reagent derived from chloromethyltrimethylsilane is a source of nucleophilic $\text{CH}_2\text{Si}(\text{CH}_3)_3$ units. Two of the most general means of synthesis of organosilanes are nucleophilic displacement of halogen from a halosilane by an organometallic reagent and addition of silanes at multiple bonds (*hydrosilation*). Organomagnesium and organolithium compounds react with trimethylsilyl chloride to give the corresponding tetrasubstituted silanes.

⁶⁶ R. K. Boeckman, Jr., D. M. Blum, B. Ganem, and N. Halvey, *Org. Synth.*, **58**, 152 (1978).

Ref. 67

Metallation of alkenes with *n*-BuLi-KOC(CH₃)₃ provides a route that is stereoselective for *Z*-allylic silanes.⁶⁸ (See p. 632 for discussion of this metallation method.)

These conditions are also applicable to functionalized systems that are compatible with metallation by this “superbase.”⁶⁹

Silicon substituents can be introduced into alkenes and alkynes by hydrosilation.⁷⁰ This reaction, in contrast to hydroboration, does not occur spontaneously, but it can be carried out in the presence of catalysts such as H₂PtCl₆, hexachloroplatinic acid. Other catalysts are also available.⁷¹ Halosilanes are more reactive than trialkylsilanes.⁷²

Alkenylsilanes can be made by Lewis acid-catalyzed hydrosilation of alkynes. Both AlCl₃ and C₂H₅AlCl₂ are effective catalysts.⁷³ The reaction proceeds by net *anti* addition, giving the *Z*-alkenylsilane. The reaction is regioselective for silylation of the terminal carbon.

⁷² T. G. Selin and R. West, *J. Am. Chem. Soc.*, **84**, 1863 (1962).

⁷³ N. Asao, T. Sudo, and Y. Yamamoto, *J. Org. Chem.*, **61**, 7654 (1996); T. Sudo, N. Asao, V. Gevorgyan, and Y. Yamamoto, *J. Org. Chem.*, **64**, 2494 (1999).

The reaction is formulated as an electrophilic attack by the aluminum halide, followed by hydride abstraction and transmetalation. A vinyl cation intermediate can account for both the regiochemistry and the stereochemistry.

A variety of transition metal complexes catalyze hydrosilylation of alkynes. Catalysis of hydrosilylation by rhodium gives *E*-alkenylsilanes from 1-alkynes.⁷⁴

Ref. 75

CpRu(CH₃CN)₃PF₆ catalyzes hydrosilylation of both terminal and internal alkynes. With this catalyst, addition exhibits the opposite regiochemistry.

With internal alkynes, the stereochemistry of addition is *anti*.

⁷⁴. R. Takeuchi, S. Nitta, and D. Watanabe, *J. Org. Chem.*, **60**, 3045 (1995).

⁷⁵. B. M. Trost and Z. T. Ball, *J. Am. Chem. Soc.*, **123**, 12726 (2001).

This method has been used to prepare alkenyl benzyldimethylsilanes.⁷⁶ These derivatives are amenable to synthetic transformation involving F⁻-mediated debenzylation.

Other ruthenium-based catalysts are also active. Ruthenium dichloride–cymene complex is stereoselective for formation of the *Z*-vinyl silanes from terminal alkynes.

Palladium-phosphine catalysts have also been used in the addition of triphenylsilane.⁷⁷ In this case, the *E*-silane is formed.

High stereoselectivity was noted with Wilkinson's catalyst in the reaction of arylalkynes with diethoxymethylsilane. Interestingly, the stereoselectivity was dependent on the order of mixing of the reagents and the catalyst. When the alkyne was added to a mixture of catalyst and silane, the *Z*-isomer was formed. Reversing the order and adding the silane to an alkyne-catalyst mixture led to formation of the *E*-product.⁷⁸

Tandem *syn* addition of alkyl and trimethylsilyl groups can be accomplished with dialkylzinc and trimethylsilyl iodide in the presence of a Pd(0) catalyst.⁷⁹

A possible mechanism involves formation of a Pd(II) intermediate that can undergo cross coupling with the zinc reagent.

Several variations of the Peterson reaction have been developed for synthesis of alkenylsilanes.⁸⁰ *E*- β -Arylvinyisilanes can be obtained by dehydration of β -silyloxy alkoxides formed by addition of lithiomethyl trimethylsilane to aromatic aldehydes. Specific Lewis acids have been found to be advantageous for the elimination step.⁸¹

Alkenylsilanes can be prepared from aldehydes and ketones using lithio(chloromethyl)trimethylsilane. The adducts are subjected to a reductive elimination by lithium naphthalenide. This procedure is stereoselective for the *E*-isomer with both alkyl and aryl aldehydes.⁸²

The adducts can be directed toward *Z*-alkenylsilanes by acetylation and reductive elimination using SmI_2 .⁸³

The stereoselectivity in this case is attributed to elimination through a cyclic TS, but is considerably reduced with aryl aldehydes.

Specialized silyl substituents have been developed. High yields of *E*-alkenylsilanes were obtained using *bis*-(dimethyl-2-pyridyl)silylmethylithium.⁸⁴ The stereoselectivity is attributed to a cyclic TS for the addition step.

If necessary for further applications, the 2-pyridyl group can be exchanged by alkyl in a two-step sequence that takes advantage of the enhanced leaving-group ability of the 2-pyridyl group.

9.2.2. General Features of Carbon-Carbon Bond-Forming Reactions of Organosilicon Compounds

Alkylsilanes are not very nucleophilic because there are no high-energy electrons in the sp^3 - sp^3 carbon-silicon bond. Most of the valuable synthetic procedures based on organosilanes involve either alkenyl or allylic silicon substituents. The dominant reactivity pattern involves attack by an electrophilic carbon intermediate at the double bond that is followed by desilylation. Attack on alkenylsilanes takes place at the α -carbon and results in overall replacement of the silicon substituent by the electrophile. Attack on allylic groups is at the γ -carbon and results in loss of the silicon substituent and an allylic shift of the double bond.

The crucial influence on the reactivity pattern in both cases is the *very high stabilization that silicon provides for carbocationic character at the β -carbon atom*. This stabilization is attributed primarily to hyperconjugation with the C–Si bond (see Part A, Section 3.4.1).⁸⁵

⁸⁴ K. Itami, T. Nokami, and J. Yoshida, *Org. Lett.*, **2**, 1299 (2000).

Most reactions of alkenyl and allylic silanes require strong carbon electrophiles and Lewis acid catalysts are often involved. The most useful electrophiles from a synthetic standpoint are carbonyl compounds, iminium ions, and electrophilic alkenes.

There are also some reactions of allylic silanes that proceed through anionic silicate species. These reactions usually involve activation by fluoride and result in transfer of an allylic anion.

Trichloro- and trifluorosilanes introduce another dimension into the reactivity of allylic silanes. The silicon in these compounds is electrophilic and can expand to pentacoordinate and hexacoordinate structures. These reactions can occur through a cyclic or chelated TS.

9.2.3. Additions Reactions with Aldehydes and Ketones

A variety of electrophilic catalysts promote the addition of allylic silanes to carbonyl compounds.⁸⁶ The original catalysts included typical Lewis acids such as TiCl_4 or BF_3 .⁸⁷ This reaction is often referred to as the *Sakurai reaction*.

These reactions involve activation of the carbonyl group by the Lewis acid. A nucleophile, either a ligand from the Lewis acid or the solvent, assists in the desilylation step.

Various other Lewis acids have been explored as catalysts, and the combination $\text{InCl}_3\text{-(CH}_3)_3\text{SiCl}$ has been found to be effective.⁸⁸ The catalysis requires both components and is attributed to assistance from O-silylation of the carbonyl compound.

Lanthanide salts, such as $\text{Sc}(\text{O}_3\text{SCF}_3)_3$, are also effective catalysts.⁸⁹

Silylating reagents such as TMSI and TMS triflate have only a modest catalytic effect, but the still more powerful silylating reagent $(\text{CH}_3)_3\text{SiB}(\text{O}_3\text{SCF}_3)_4$ does induce addition to aldehydes.⁹⁰

In another procedure, $(\text{CH}_3)_3\text{SiN}(\text{O}_3\text{SCF}_3)$ is generated in situ from triflimide.⁹¹

These reagents initiate a catalytic cycle that regenerates the active silylation species.⁹² (See p. 83 for a similar cycle in the Mukaiyama reaction.)

Although the allylation reaction is formally analogous to the addition of allylic boranes to carbonyl derivatives, it does not normally occur through a cyclic TS. This is because, in contrast to the boranes, the silicon in allylic silanes has little Lewis acid character and does not coordinate at the carbonyl oxygen. The stereochemistry of addition of allylic silanes to carbonyl compounds is consistent with an acyclic TS. The *E*-stereoisomer of 2-butenyl(trimethyl)silane gives nearly exclusively the product in

which the newly formed hydroxyl group is *syn* to the methyl substituent; the *Z*-isomer is also modestly selective for the *syn* isomer.⁹³

Both *anti*-synclinal and *anti*-periplanar TSs are considered to be feasible. These differ in the relative orientation of the C=C and C=O bonds. The *anti*-synclinal arrangement is usually preferred.⁹⁴

The addition reaction of allylsilane to acetaldehyde with BF_3 as the Lewis acid has been modeled computationally.⁹⁵ The lowest-energy TSs found, which are shown in Figure 9.2, were of the synclinal type, with dihedral angles near 60° . Although the structures are acyclic, there is an apparent electrostatic attraction between the fluorine and the silicon that imparts some cyclic character to the TS. Both *anti* and *syn* structures were of comparable energy for the model. However, steric effects that arise by replacement of hydrogen on silicon with methyl are likely to favor the *anti* TS.

When chiral aldehydes such as **6** are used, there is a modest degree of diastereoselectivity in the direction predicted by an open Felkin TS.⁹⁶

Aldehydes with α - or β -benzyloxy substituents react with allyltrimethylsilane in the presence of SnCl_4 to give high yields of product resulting from chelation control.⁹⁷

⁹⁷ C. H. Heathcock, S. Kiyooka, and T. Blumenkopf, *J. Org. Chem.*, **49**, 4214 (1984).

The stereochemistry is consistent with approach of the silane *anti* to the methyl substituent.

In contrast, BF_3 showed very low stereoselectivity, consistent with its inability to form a chelate.

Intramolecular reactions can also occur between carbonyl groups and allylic silanes. These reactions frequently show good stereoselectivity. For example, **7** cyclizes primarily to **8** with 4% of **9** as a by-product. The two other possible stereoisomers are not observed.⁹⁸ The stereoselectivity is attributed to a preference for TS **7A** over TS **7B**. These are both synclinal structures but differ stereoelectronically. In **7A**, the electron flow is approximately *anti* parallel, whereas in **7B** it is skewed. It was suggested that this difference may be the origin of the stereoselectivity.

The differential in chelation capacity between BF_3 and SnCl_4 was used to control the stereochemistry of the cyclization of the vinyl silane **10**.⁹⁹ With BF_3 , the reaction proceeds through a nonchelated TS and the stereochemistry at the new bond is *trans*. With SnCl_4 , a chelated TS leads to the *cis* diastereomer.

Both ketals¹⁰⁰ and enol ethers¹⁰¹ can be used as electrophiles in place of aldehydes with appropriate catalysts. Trimethylsilyl iodide can be used in catalytic quantities

because it is regenerated by recombination of iodide ion with silicon in the desilylation step.¹⁰²

This type of reaction has been used for the extension of the carbon chain of protected carbohydrate acetals.¹⁰³

Reaction of allylic silanes with enantiomerically pure 1,3-dioxanes has been found to proceed with moderate enantioselectivity.¹⁰⁴ The homoallylic alcohol can be liberated by oxidation followed by base-catalyzed β -elimination. The alcohols obtained in this way are formed in $70 \pm 5\%$ e.e.

The enantioselectivity is dependent on several reaction variables, including the Lewis acid and the solvent. The observed stereoselectivity appears to reflect differences in the precise structure of the electrophilic species generated. Mild Lewis acids tend to react with inversion of configuration at the reaction site, whereas very strong Lewis acids cause loss of enantioselectivity. The strength of the Lewis acid, together with related effects of solvent and other experimental variables, determines the nature of the electrophile. With mild Lewis acids, a tight ion pair favors inversion, whereas stronger Lewis acids cause complete dissociation to an acyclic species. These two species represent extremes of behavior and intermediate levels of enantioselectivity are also observed.¹⁰⁵

Although most studies of alkenyl and allylic silanes have been done with trialkylsilyl analogs, the reactivity of the system can be adjusted by varying the silicon substituents. Allylic trichlorosilanes react with aldehydes in DMF to give homoallylic alcohols.¹⁰⁶ The reactions are highly stereoselective with respect to the silane geometry and give the product expected for a cyclic TS. The reaction is thought to proceed through a hexacoordinate silicon intermediate.

Allylic trichlorosilanes have shown promise in the development of methods for enantioselective reactions by use of chiral phosphoramides such as **C**.

Mechanistic studies suggested that two phosphoramidate molecules were involved.¹⁰⁷ This led to the development of linked phosphoramidates such as **D**.¹⁰⁸

The axially chiral 2,2'-bipyridine **E** is also an effective enantioselective catalyst for addition of allyltrimethylsilane to aldehydes.¹⁰⁹

The use of trifluorosilanes permits reactions through hexacoordinate silicon, which presents an opportunity for chelation control. For example, α -hydroxy ketones give *syn* diols.¹¹⁰

Advantage of this chelation has been taken in the construction of compounds with several contiguous chiral centers. *Z*-2-Butenyl trifluorosilanes give *syn*-1,3-diols on reaction with *anti*- β -hydroxy- α -methyl aldehydes.¹¹¹ The stereoselectivity is consistent with a chelated bicyclic TS.

This methodology was applied to construct the all *anti* stereochemistry for a segment of the antibiotic zincophorin.

The corresponding *syn*- β -hydroxy- α -methyl aldehydes do not react through a chelated TS,¹¹² which appears to be due to steric factors that raise the bicyclic TS by several kcal relative to the *anti* isomers. The monocyclic six-membered TS does not incorporate these factors and the *syn* isomer reacts through a monocyclic TS. Figure 9.3 depicts the competing TSs and their relative energies as determined by MNDO calculations.

The electrophilicity of silicon is enhanced in five-membered ring structures. Chloro dioxasilolanes, oxazasilolidines, and diazasilolidines react with aldehydes in the absence of an external Lewis acid catalyst.¹¹³

Comparison of chelated bicyclic and nonchelated monocyclic transition structures for addition of allyl trifluorosilane to *syn*- and *anti*-3-methoxy-2,4-dimethylpentanal based on MNDO computations: (a) chelated bicyclic transition structures differ by 6 kcal/mol owing to nonbonded interactions in the *syn* case; (b) nonchelated monocyclic transition structures are of comparable energy for both isomers. Reproduced from *J. Org. Chem.*, **68**, 1319 (2003), by permission of the American Chemical Society.

The oxazasilolidine derived from pseudoephedrine incorporates chirality around the silicon and leads to enantioselective addition.

While trifluoro and other halosilanes function by increased *electrophilicity* at silicon, *nucleophilic* reactivity of allylic silanes can be enhanced by formation of anionic adducts (silicates). Reaction of allylic silanes with aldehydes and ketones can

p-Tol-BINAP-AgF effects enantioselective additions with trimethoxysilanes.¹¹⁹ These reactions give *anti* products, regardless of the configuration of the allylic silane.

The combination BINAP-Ag₂O-KF with 18-crown-6 also leads to high enantioselectivity.¹²⁰

9.2.4. Reactions with Iminium Ions

Iminium ions are reactive electrophiles toward both alkenyl and allylic silanes. Useful techniques for closing nitrogen-containing rings are based on in situ generation of iminium ions from amines and formaldehyde.¹²¹

When primary amines are employed, the initially formed 3-butenylamine undergoes a further reaction forming 4-piperidinols.¹²²

Reactions of this type can also be observed with 4-(trimethylsilyl)-3-alkenylamines.¹²³

Mechanistic investigation in this case has shown that there is an equilibrium between an alkenyl silane and an allylic silane by a rapid 3,3-sigmatropic process. The cyclization occurs through the more reactive allylic silane.

¹²³ C. Flann, T. C. Malone, and L. E. Overman, *J. Am. Chem. Soc.*, **109**, 6097 (1987).

N-Acyliminium ions, which are even more reactive toward allylic and alkenylsilanes, are usually obtained from imides by partial reduction (see Section 2.2.2). The partially reduced *N*-acylcarbinolamines can then generate acyliminium ions. Such reactions have been employed in intramolecular situations with both allylic and vinyl silanes.

9.2.5. Acylation Reactions

Reaction of alkenyl silanes with acid chlorides is catalyzed by aluminum chloride or stannic chloride.¹²⁶

Titanium tetrachloride induces reaction with dichloromethyl methyl ether to give α , β -unsaturated aldehydes.¹²⁷

Similar conditions are used to effect reactions of allylsilanes with acyl halides, resulting in β , γ -unsaturated ketones.¹²⁸

Indium tribromide also gives good yields, with minor isomerization to the α,β -isomers.¹²⁹

These reactions probably involve acylium ions as the electrophiles.

Scheme 9.4 shows some representative reactions of allylic and alkenyl silanes. Entry 1 involves 3-trimethylsilylcyclopentene, which can be made by hydrosilylation of cyclopentadiene by chlorodimethylsilane, followed by reaction with methylmagnesium bromide.

Entry 2 was reported as part of a study of the stereochemistry of addition of allyltrimethylsilane to protected carbohydrates. Use of BF_3 as the Lewis acid, as shown, gave the product from an open TS, whereas TiCl_4 led to the formation of the alternate stereoisomer through chelation control. Similar results were reported for a protected galactose.

In Entry 3, BF_3 -mediated addition exhibits a preference for the Felkin stereochemistry.

Entries 4 and 5 are examples of use of the Sakurai reaction to couple major fragments in multistage synthesis. In Entry 4 an unusual catalyst, a chiral acyloxyboronate (see p. 126) was used to effect an enantioselective coupling. (See p. 847 for another application of this catalyst.) Entry 5 was used in the construction of amphidinolide P, a compound with anticancer activity.

Entries 6 to 8 demonstrate addition of allyl trimethylsilane to protected carbohydrate acetals. This reaction can be a valuable method for incorporating the chirality of carbohydrates into longer carbon chains. In cases involving cyclic acetals, reactions occur through oxonium ions and the stereochemistry is governed by steric and stereo-electronic effects of the ring. Note that Entry 8 involves the use of trimethylsilyl

triflate as the catalyst. Entry 9 is a case of substrate control of enantioselectivity. Both high diastereoselectivity and enantioselectivity at the new chiral center were observed. The reaction is believed to proceed through an *O*-methyloxonium and to involve an open TS. Entry 10 involves generation of a cyclic oxonium ion. The observed stereochemistry is consistent with a synclinal orientation in the TS.

Entries 11 to 13 are examples of iminium ion and acyliminium ion reactions. Note that in Entries 11 and 12, vinyl, rather than allylic, silane moieties are involved. Entries 14 and 15 illustrate the synthesis of β , γ -unsaturated ketones by acylation of allylic silanes.

9.2.6. Conjugate Addition Reactions

Allylic silanes act as nucleophilic species toward α , β -unsaturated ketones in the presence of Lewis acids such as TiCl_4 .¹³⁰

The stereochemistry of this reaction in cyclic systems is in accord with expectations for stereoelectronic control. The allylic group approaches from a trajectory that is appropriate for interaction with the LUMO of the conjugated system.¹³¹

The stereoselectivity then depends on the conformation of the enone and the location of substituents that establish a steric bias for one of the two potential directions of approach. In the ketone **11**, the preferred approach is from the β -face, since this permits maintaining a chair conformation as the reaction proceeds.¹³²

¹³⁰. A. Hosomi and H. Sakurai, *J. Am. Chem. Soc.*, **99**, 1673 (1977).

¹³². W. R. Roush and A. E. Walts, *J. Am. Chem. Soc.*, **106**, 721 (1984).

Conjugate addition to acyclic enones is subject to chelation control when TiCl_4 is used as the Lewis acid. Thus, whereas the *E*-enone **12** gives *syn* product **13** via an acyclic TS, the *Z*-isomer **14** reacts through a chelated TS to give **15**.¹³³

Conjugate additions of allylic silanes to enones are also catalyzed by InCl_3 -TMSCl.¹³⁴

The reaction can also be carried out using indium metal. Under these conditions InCl_3 is presumably generated in situ.¹³⁵

Conjugate addition can also be carried out by fluoride-mediated disilylation. A variety of α,β -unsaturated esters and amides have been found to undergo this reaction.¹³⁶

With unsaturated aldehydes, 1,2-addition occurs and with ketones both the 1,2- and 1,4-products are formed.

Some examples of conjugate addition reactions of allylic silanes are given in Scheme 9.5. Entries 1 to 3 illustrate the synthesis of several β -allyl ketones. Note that Entry 2 involves the creation of a quaternary carbon. Entry 4 was used in the synthesis of a terpenoid ketone, (+)-nootkatone. Entry 5 illustrates fluoride-mediated addition using tetrabutylammonium fluoride. These conditions were found to be especially effective for unsaturated esters. In Entry 6, the addition is from the convex face of the ring system. Entry 7 illustrates a ring closure by intramolecular conjugate addition.

9.3. Organotin Compounds

9.3.1. Synthesis of Organostannanes

The readily available organotin compounds include tin hydrides (stannanes) and the corresponding chlorides, with the tri-*n*-butyl compounds being the most common. Trialkylstannanes can be added to carbon-carbon double and triple bonds. The reaction is usually carried out by a radical chain process,¹³⁷ and the addition is facilitated by the presence of radical-stabilizing substituents.

With terminal alkynes, the stannyl group is added at the unsubstituted carbon and the *Z*-stereoisomer is initially formed but is readily isomerized to the *E*-isomer.¹⁴⁰

The reaction with internal acetylenes leads to a mixture of both regioisomers and stereoisomers.¹⁴¹

Lewis acid-catalyzed hydrostannylation has been observed using ZrCl_4 . With terminal alkynes the *Z*-alkenylstannane is formed.¹⁴² These reactions are probably similar in mechanism to Lewis acid-catalyzed additions of silanes (see p. 811).

¹⁴². N. Asao, J.-X. Liu, T. Sudoh, and Y. Yamamoto, *J. Org. Chem.*, **61**, 4568 (1996).

Palladium-catalyzed procedures have also been developed for addition of stannanes to alkynes,¹⁴³ and these reactions usually occur by *syn* addition.

Hydrostannylation of terminal alkynes can also be achieved by reaction with stannyl-cyanocuprates.

Ref. 144

Ref. 145

These reactions proceed via a *syn* addition followed by protonolysis.

Allylic stannanes can be prepared from allylic halides and sulfonates by displacement with or LiSnMe_3 or LiSnBu_3 .¹⁴⁶ They can also be prepared by Pd-catalyzed substitution of allylic acetates and phosphates using $(\text{C}_2\text{H}_5)_2\text{AlSn}(n\text{-C}_4\text{H}_9)_3$.¹⁴⁷

Another major route for synthesis of stannanes is reaction of an organometallic reagent with a trisubstituted halostannane, which is the normal route for the preparation of aryl stannanes.

Ref. 149

There are several procedures for synthesis of terminal alkenyl stannanes that involve addition to aldehydes. A well-established three-step sequence culminates in a radical addition to a terminal alkyne.¹⁵⁰

Another sequence involves a dibromomethyl(trialkyl)stannane as the starting material. On reaction with CrCl_2 , addition to the aldehyde is followed by reductive elimination.¹⁵¹

Deprotonated trialkylstannanes are potent nucleophiles. Addition to carbonyl groups or iminium intermediates provides routes to α -alkoxy- and α -amino-alkylstannanes.

α -Silyoxystannanes can be prepared directly from aldehydes and tri-*n*-butyl (trimethylsilyl)stannane.¹⁵⁴

Addition of tri-*n*-butylstannyllithium to aldehydes followed by iodination and dehydrohalogenation gives primarily *E*-alkenylstannanes.¹⁵⁵

9.3.2. Carbon-Carbon Bond-Forming Reactions

As with the silanes, the most useful synthetic procedures involve electrophilic attack on alkenyl and allylic stannanes. The stannanes are considerably more reactive than the corresponding silanes because there is more anionic character on carbon in the C–Sn bond and it is a weaker bond.¹⁵⁶ The most useful reactions in terms of syntheses involve the Lewis acid-catalyzed addition of allylic stannanes to aldehydes.¹⁵⁷ The reaction occurs with allylic transposition.

There are also useful synthetic procedures in which organotin compounds act as carbanion donors in transition metal-catalyzed reactions, as discussed in Section 8.2.3.3. Organotin compounds are also very important in free radical reactions, as is discussed in Chapter 10.

9.3.2.1. Reactions of Allylic Trialkylstannanes. Allylic organotin compounds are not sufficiently reactive to add directly to aldehydes or ketones, although reactions with aldehydes do occur with heating.

Ref. 158

Use of Lewis acid catalysts allows allylic stannanes to react under mild conditions. As is the case with allylic silanes, a double-bond transposition occurs in conjunction with destannylation.¹⁵⁹

The stereoselectivity of addition to aldehydes has been of considerable interest.¹⁶⁰ With benzaldehyde the addition of 2-butenylstannanes catalyzed by BF_3 gives the *syn* isomer, irrespective of the stereochemistry of the butenyl group.¹⁶¹

Synclinal and antiperiplanar conformations of the TS are possible. The two TSs are believed to be close in energy and either may be involved in individual systems. An electronic π interaction between the stannane HOMO and the carbonyl LUMO, as well as polar effects appear to favor the synclinal TS and can overcome the unfavorable steric effects.^{161b, 162} Generally the synclinal TS seems to be preferred for intramolecular reactions. The steric effects that favor the antiperiplanar TS are not present in intramolecular reactions, since the aldehyde and the stannane substituents are then part of the intramolecular linkage.

With chiral aldehydes, reagent approach is generally consistent with a Felkin model.¹⁶³ This preference can be reinforced or opposed by the effect of other stereocenters. For example, the addition of allyl stannane to 1,4-dimethyl-3-(4-methoxybenzyloxy)pentanal is strongly in accord with the Felkin model for the *anti* stereoisomer but is anti-Felkin for the *syn* isomer.

When an aldehyde subject to chelation control is used, the *syn* stereoisomer dominates, with MgBr_2 as the Lewis acid.¹⁶⁴

The introduction of a β -methyl group shifts the stereoselectivity to *anti*, indicating a preference for TS **E**. There is some dependence on the Lewis acid. For example, the reaction below gives a high ratio of chelation control with MgBr_2 and SnCl_4 , but not with TiCl_4 .¹⁶⁵

β -Oxy substituents can also lead to chelation control. Excellent stereoselectivity is observed using SnCl_4 at low temperature.¹⁶⁶

The chelation control approach has been used during the synthesis of the C(13)–C(19) fragment of a marine natural product called calculin A-D.¹⁶⁷

9.3.2.2. Reactions of Allylic Halostannanes. Various allyl halostannanes can transfer allyl groups to carbonyl compounds. In this case the reagent acts both as a Lewis acid and as the source of the nucleophilic allyl group. Reactions involving halostannanes are believed to proceed through cyclic TSs.

¹⁶⁷. O. Hara, Y. Hamada, and T. Shiori, *Synlett*, 283 285 (1991).

Ref. 168

The halostannanes can also be generated in situ by reactions of allylic halides with tin metal or stannous halides.

Ref. 169

Ref. 169

The allylation reaction can be adapted to the synthesis of terminal dienes by using 1-bromo-3-iodopropene and stannous chloride. The elimination step is a reductive elimination of the type discussed in Section 5.8. Excess stannous chloride acts as the reducing agent.

Ref. 170

Allylic Sn(II) species are believed to be involved in reactions of allylic trialkyl stannanes in the presence of SnCl₂. These reactions are particularly effective in acetonitrile, which appears to promote the exchange reaction. Ketones as well as aldehydes are reactive under these conditions.¹⁷¹

¹⁶⁸. T. Mukaiyama and T. Harada, *Chem. Lett.*, 1527 (1981).

¹⁶⁹. T. Mukaiyama, T. Harada, and S. Shoda, *Chem. Lett.*, 1507 (1980).

¹⁷⁰. J. Auge, *Tetrahedron Lett.*, **26**, 753 (1985).

¹⁷¹. (a) M. Yasuda, Y. Sugawa, A. Yamamoto, I. Shibata, and A. Baba, *Tetrahedron Lett.*, **37**, 5951 (1996); (b) M. Yasuda, K. Hirata, M. Nishino, A. Yamamoto, and A. Baba, *J. Am. Chem. Soc.*, **124**, 13442 (2002).

The *anti* stereochemistry is consistent with a cyclic TS, but the reaction is stereoconvergent for the *E*- and *Z*-2-butenylstannanes, indicating that isomerization must occur at the transmetallation stage. The adducts are equilibrated at 82°C and under these conditions the *anti* product is isolated on workup.

Cyclic allylstannanes give *syn* products with high selectivity.

The reaction with α -hydroxy and α -methoxy ketones under these conditions are chelation controlled.

Use of di-(*n*-butyl)stannyl dichloride along with an acyl or silyl halide leads to addition of allylstannanes to the aldehydes.^{172a, 172} Reaction is also promoted by butylstannyl trichloride.¹⁷³ Both SnCl_4 and SnCl_2 also catalyze this kind of addition.

¹⁷² J. K. Whitesell and R. Apodaca, *Tetrahedron Lett.*, **37**, 3955 (1996).

¹⁷³ H. Miyake and K. Yamamura, *Chem. Lett.*, 1369 (1992); H. Miyake and K. Yamamura, *Chem. Lett.*, 1473 (1993).

Reactions of tetraallylstannanes with aldehydes catalyzed by SnCl_4 also appear to involve a halostannane intermediate. It can be demonstrated by NMR that there is a rapid redistribution of the allyl group.¹⁷⁴ Reactions with these halostannanes are believed to proceed through a cyclic TS.

9.3.2.3. Reactions Involving Transmetallation. With certain Lewis acids, the reaction may involve a prior transmetallation. This introduces several additional factors into the analysis of the stereoselectivity, as the stereochemistry of the transmetallation has to be considered. Reactions involving halotitanium and halotin intermediates formed by transmetallation can react through a cyclic TS. When TiCl_4 is used as the catalyst, the stereoselectivity depends on the order of addition of the reagents. When *E*-2-butenylstannane is added to a TiCl_4 -aldehyde mixture, *syn* stereoselectivity is observed. When the aldehyde is added to a premixed solution of the 2-butenylstannane and TiCl_4 , the *anti* isomer predominates.¹⁷⁵

The formation of the *anti* stereoisomer is attributed to involvement of a butenyltitanium intermediate formed by rapid exchange with the butenylstannane. This intermediate then reacts through a cyclic TS.

Indium chloride in polar solvents such as acetone or acetonitrile leads to good diastereoselectivity with cyclohexanecarboxaldehyde and other representative aldehydes.¹⁷⁶

¹⁷⁴ S. E. Denmark, T. Wilson, and T. M. Willson, *J. Am. Chem. Soc.*, **110**, 984 (1988); G. E. Keck, M. B. Andrus, and S. Castellino, *J. Am. Chem. Soc.*, **111**, 8136 (1989).

¹⁷⁵ G. E. Keck, D. E. Abbott, E. P. Boden, and E. J. Enholm, *Tetrahedron Lett.*, **25**, 3927 (1984).

¹⁷⁶ J. A. Marshall and K. W. Hinkle, *J. Org. Chem.*, **60**, 1920 (1995).

These reactions are believed to proceed via transmetallation. Configurational inversion occurs at both the transmetallation and addition steps, leading to overall retention of the allylic stereochemistry.

These reagents are useful in enantioselective synthesis and are discussed further in the following section.

9.3.2.4. γ -Oxygen-Substituted Stannanes. Oxygenated allylic stannanes have been synthesized and used advantageously in several types of syntheses. Both α - and γ -alkoxy and silyloxy stannane can be prepared by several complementary methods.¹⁷⁷ *E*- γ -Alkoxy and silyloxy allylic stannanes react with aldehydes to give primarily *syn* adducts.¹⁷⁸

Allylic silanes with γ -alkoxy substituents also give a preference for the *syn* stereochemistry.¹⁷⁹

Improved stereoselectivity is observed with methoxymethoxy (MOM) and TBDMSO substituents.¹⁸⁰

¹⁷⁷ J. A. Marshall, *Chem. Rev.*, **96**, 31 (1996).

¹⁷⁸ J. A. Marshall, J. A. Jablonowski, and L. M. Elliott, *J. Org. Chem.*, **60**, 2662 (1995).

¹⁷⁹ M. Koreeda and Y. Tanaka, *Tetrahedron Lett.*, **28**, 143 (1987).

¹⁸⁰ J. A. Marshall and J. A. Welmaker, *J. Org. Chem.*, **57**, 7158 (1992).

Use of oxygenated stannanes with α -substituted aldehydes leads to matched and mismatched combinations.¹⁸¹ For example, with the γ -MOM derivative and α -benzyloxypropanal, the matched pair gives a single stereoisomer of the major product, whereas the mismatched pair gives a 67:33 *syn:anti* mixture. The configuration at the alkoxy-substituted center is completely controlled by the chirality of the stannane.

Use of MgBr_2 , which results in chelation control, reverses the matched and mismatched combinations.

9.3.2.5. Enantioselective Addition Reactions of Allylic Stannanes. There have been several studies of the enantiomers of α -oxygenated alkenyl stannanes. The chirality of the α -carbon exerts powerful control on enantioselectivity with the preference for the stannyl group to be *anti* to the forming bond. This is presumably related to the stereoelectronic effect that facilitates the transfer of electron density from the tin to the forming double bond.¹⁸²

¹⁸¹ J. A. Marshall, J. A. Jablonowski, and G. P. Luke, *J. Org. Chem.*, **59**, 7825 (1994).

¹⁸² J. A. Marshall and W. Y. Gung, *Tetrahedron*, **45**, 1043 (1989).

Allylic stannanes with γ -oxygen substituents have been used to build up polyoxygenated carbon chains. For example, **16** reacts with the stannane **17** to give a high preference for the stereoisomer in which the two oxygen substituents are *anti*. This stereoselectivity is consistent with chelation control.¹⁸³

The substrate-controlled addition of **18** to **19** proceeded with good enantioselectivity and was used to prepare the epoxide (+)-dispalure, a gypsy moth pheromone.¹⁸⁴

Reagent-controlled stereoselectivity can provide stereochemical relationships over several centers when a combination of acyclic and chelation control and cyclic TS resulting from transmetalation is utilized. In reactions mediated by BF_3 or MgBr_2 the new centers are *syn*. Indium reagents can be used to create an *anti* relationship between two new chiral centers. The indium reagents are formed by transmetalation and react

¹⁸³ G. E. Keck, K. A. Savin, E. N. K. Cressman, and D. E. Abbott, *J. Org. Chem.*, **59**, 7889 (1994).

¹⁸⁴ J. A. Marshall, J. A. Jablonowski, and H. Jiang, *J. Org. Chem.*, **64**, 2152 (1999).

through cyclic TSs leading to *anti* stereochemistry at the new bond. The complementary relationship has been used to construct all eight possible hexose configurations.¹⁸⁵

More remote oxygen substituents can also influence stereochemistry. 4-Benzyloxy-2-pentenyl tri-*n*-butylstannane exhibits excellent enantioselectivity in reactions with aldehydes.¹⁸⁶ This reaction is believed to involve chelation of the

¹⁸⁵ J. A. Marshall and K. W. Hinkle, *J. Org. Chem.*, **61**, 105 (1996).

¹⁸⁶ E. J. Thomas, *J. Chem. Soc. Chem. Commun.*, 411 (1997); A. H. McNeill and E. J. Thomas, *Synthesis*, 322 (1998).

benzyloxy group in both the transmetallation and addition steps. The transmetallation is thought to involve coordination with SnCl_4 through the benzyloxy group that is maintained in the addition step.

Allylstannane additions to aldehydes can be made enantioselective by use of chiral catalysts. A catalyst prepared from the chiral binaphthols *R*- or *S*-BINOL and $\text{Ti}(\text{O-}i\text{-Pr})_4$ achieves 85–95% enantioselectivity.¹⁸⁷

BINAP-AgF gives good enantioselectivity, especially for the major *anti* product in the addition of 2-butenylstannanes to benzaldehyde.¹⁸⁸ This system appears to be stereoconvergent, suggesting that isomerization of the 2-butenyl system occurs, perhaps by transmetallation.

BF_3 should involve an open TS. The observed stereochemistry is *syn* but the approach is anti-Felkin.

Entry 9 was used in the synthesis of a furanocembranolide. This reaction presumably proceeds through a trichlorostannane intermediate and involves allylic

shift at both the transmetalation and addition steps, resulting in restoration of the original allylic structure.

Entry 10 was used in conjunction with dihydroxylation in the enantiospecific synthesis of polyols. Entry 11 illustrates the use of SnCl_2 with a protected polypropionate. Entries 12 and 13 result in the formation of lactones, after MgBr_2 -catalyzed additions to heterocyclic aldehyde having ester substituents. The stereochemistry of both of these reactions is consistent with approach to a chelate involving the aldehyde oxygen and oxazoline oxygen.

9.3.2.6. Allenyl Stannanes. Allenyl stannanes are a useful variation of the allylic stannanes.¹⁹² They can be made in enantiomerically pure form by S_N2' displacements on propargyl tosylates.¹⁹³

The allenyl stannanes react with aldehydes under the influence of Lewis acids such as BF_3 and MgBr_2 . Unbranched aldehydes are not very stereoselective, but branched aldehydes show a strong preference for the *syn* adduct.

With α -benzyloxypropanal, using MgBr_2 as the Lewis acid, chelation control is observed. The stereospecificity is determined by an *anti* orientation of the C–Sn bond

¹⁹² J. A. Marshall, *Chem. Rev.*, **96**, 31 (1996).

¹⁹³ J. A. Marshall and X. Wang, *J. Org. Chem.*, **56**, 3211 (1991).

and the forming C–C bond. As a result, the (*S*) reactant gives a *syn* adduct, whereas the (*R*) reactant gives the *anti* isomer.

The allenic stannanes can be transmetallated by treatment with SnCl₄, a reaction that results in the formation of the a propargyl stannane. If the transmetallation reaction is allowed to equilibrate at 0°C, an allenic structure is formed. These reagents add stereospecifically to the aldehyde through cyclic TSs.¹⁹⁴

The combination of reagents and methods can provide for stereochemical control of addition to α -substituted aldehydes.¹⁹⁵ An application of the methodology can be found in the synthesis of (+)-discodermolide that was carried out by J. A. Marshall and co-workers and is described in Scheme 13.69.

9.4. Summary of Stereoselectivity Patterns

In this chapter, we have seen a number of instances of stereoselectivity. Although they are affected by specific substitution patterns, every case can be recognized as conforming to one of several general patterns.

1. Reactions proceeding through a monocyclic TS with substrate control: These reactions exhibit predictable stereoselectivity determined by the monocyclic

¹⁹⁴. J. A. Marshall and J. Perkins, *J. Org. Chem.*, **60**, 3509 (1995).

¹⁹⁵. J. A. Marshall, J. F. Perkins, and M. A. Wolf, *J. Org. Chem.*, **60**, 5556 (1995).

Scheme 9.7. Summary of Stereoselectivity of Allylic Reagents in Carbonyl Addition Reactions

Monocyclic TS	Open TS	Chelation TS	Stereoconvergent
Allylboration with β -allylic boranes and boronates	Lewis acid-catalyzed addition of allylic silanes	Lewis acid-catalyzed addition of allylic silanes and stannanes α - and β -oxy aldehydes	SnCl_2 -mediated addition of allylic to stannanes aryl methyl ketones
Addition of allylic trihalo stannanes to aldehydes	Lewis Acid-catalyzed addition of allylic stannanes		

TS, which is usually based on the chair (Zimmerman-Traxler) model. This pattern is particularly prevalent for the allylic borane reagents, where the Lewis acidity of boron promotes a tight cyclic TS, but at the same time limits the possibility of additional chelation. The dominant factors in these cases are the *E*- or *Z*-configuration of the allylic reagent and the conformational preferences of the reacting aldehyde (e.g., a Felkin-type preference.)

2. Reactions proceeding through open TS: In this group, exemplified by BF_3 -catalyzed additions of allylic silanes and stannanes, the degree of stereochemical control is variable and often moderate. The stereoselectivity depends on steric factors in the open TS and can differ significantly for the *E*- and *Z*-isomers of the allylic reactant.
3. Reactions through chelated TS: Reactions of α - or β -oxy-substituted aldehydes often show chelation-controlled stereoselectivity with Lewis acids that can accommodate five or six ligands. Chelation with substituents in the allylic reactant can also occur. The overall stereoselectivity depends on steric and stereoelectronic effects in the chelated TS.
4. Stereoconvergence owing to reactant or product equilibration: We also saw several cases where the product composition was the same for stereoisomeric reactants, e.g., for *E*- and *Z*-allylic reactants. This can occur if there is an intermediate step in the mechanism that permits *E*- and *Z*-equilibration or if the final stereoisomeric product can attain equilibrium.

Scheme 9.7 gives examples of each of these types of stereoselectivities. The analysis of any particular system involves determination of the nature of the reactant, e.g., has transmetallation occurred, the coordination capacity of the Lewis acid, and the specific steric and stereoelectronic features of the two reactants.

Problems

(References for these problems will be found on page 1286.)

9.1. Give the expected product(s) for the following reactions:

9.2. Starting with an alkene $\text{RCH}=\text{CH}_2$, indicate how an organoborane intermediate could be used for each of the following synthetic transformations:

- 9.3. Scheme 9.1 describes reactions with several lithiated compounds, including dichloromethane, dichloromethyl methyl ether, phenylthiomethyl methyl ether, and phenylthioacetals. Compare the structure of these reagents and the final products for these reactions. Develop a mechanistic outline that encompasses these reactions. Discuss the features that these reagents have in common with one another and with carbon monoxide.
- 9.4. Each of the following transformations was performed advantageously with a thexylborane derivative. Give appropriate reactants, reagents, and reaction conditions for effecting the following syntheses in a one-pot" process.

- 9.5. Provide mechanisms for the formation of the new carbon-carbon bonds in each of the following reactions:

- a. When the *E*- and *Z*-isomers of 2-butenyl-1,3,2-dioxaborolane **6-A** react with aldehyde **6-B**, the *Z*-isomer gives *syn* product **6-C** with greater than 90% stereoselectivity. The *E*-isomer, however, gives a nearly 1:1 mixture of two *anti* products **6-D** and **6-E**.

- b. The reaction of several $\Delta^{2,3}$ -pyranyl acetates with allyl trimethylsilane under the influence of Lewis acids gives 2-allyl- $\Delta^{3,4}$ -pyrans. The stereochemistry depends on whether the *E*- or *Z*-allylsilane is used. There is a preference for *anti* stereochemistry at the new bond with the *E*-silane but *syn* stereochemistry with the *Z*-silane. The preference for the *syn* stereochemistry is increased by use of a more bulky silyl substituent. Analyze the competing transition structures for the *E*- and *Z*-silanes and suggest an explanation for the observed stereoselectivity.

- c. In the reaction of 2-pentenyl tri-*n*-butylstannanes with benzaldehyde and BF_3 , the diastereoselectivity is dependent on the identity of the 3-substituent group. Offer an explanation in terms of possible transition structures.

- d. It is observed that the stereoselectivity of cyclizative condensation of aminoalkyl silane **6-F** depends on the steric bulk of the amino substituent. Offer an explanation for this observation in terms of the transition structure for the addition reaction.

R	Yield (%)	trans:cis ratio
CH ₃ ^a	68	20:80
PhCH ₂	88	58:42
Ph ₂ CH	73	>99:1
Dibenzocycloheptyl	67	>99:1

^a Ph(CH₃)₂Si instead of (CH₃)₃Si.

- 9.7. A number of procedures for stereoselective synthesis of alkenes involving alkenylboranes have been developed. For each of the reactions given below, show the structure of the intermediates and outline the mechanism in sufficient detail to account for the observed stereoselectivity.

- 9.8. Suggest reagents and reaction conditions that would be effective for the following cyclization reactions:

9.9. Show how the following silanes and stannanes can be synthesized from the suggested starting material.

- (a)  from 
- (b)  from $\text{CH}_3\text{CH}_2\text{C}\equiv\text{CCO}_2\text{C}_2\text{H}_5$
- (c) $\text{Bu}_3\text{SnCH}=\text{CHSnBu}_3$ from $\text{HC}\equiv\text{CH}$, Bu_3SnCl , and Bu_3SnH
- (d)  from 
- (e)  from RCOCl or $\text{RCO}_2\text{R}'$
- (f)  from 

9.10. Each of the unsaturated cyclic amines shown below has been synthesized by reaction of an amino-substituted allylic silane under iminium ion cyclization conditions ($\text{CH}_2=\text{O}$, TFA). By retrosynthetic analysis, identify the appropriate precursor for each cyclization. Suggest a method of synthesis of each of the required amines.

9.11. Both *E*- and *Z*-isomers of the terpene γ -bisabolene have been isolated from natural sources. The synthesis of these compounds can be achieved by stereoselective alkene syntheses using borane intermediates. An outline of each synthesis is given below. Indicate the reaction conditions that would permit the stereoselective synthesis of each isomer.

9.12. By retrosynthetic analysis, devise a sequence of reactions that would provide the desired compound from the indicated starting materials.

9.13. Show how the following compounds could be prepared in high enantiomeric purity using enantiopure boranes as reactants.

9.14. Show how organoborane intermediates can be used to synthesize the gypsy moth pheromone *E, Z*-CH₃CO₂(CH₂)₄CH=CH(CH₂)₂CH=CH(CH₂)₃CH₃ from hept-6-ynyl acetate, allyl bromide, and 1-hexyne.

9.15. Predict the major stereoisomer that will be formed in the following reactions. Show the transition structure that is the basis for your response.

- 9.16. The stereoselectivity of the β -carboethoxyallylic boronate derived from the *endo*-phenyl auxiliary **A** (p. 803) toward *R*- and *S*-glyceraldehyde acetonide has been investigated. One enantiomer gives the *anti* product in 98:2 ratio, whereas the other favors the *syn* product by a 65:35 ratio. Based on the proposed transition structure for this boronate, determine which combination leads to the higher stereoselectivity and which to the lower. Propose the favored transition structure in each case.
- 9.17. The *R*- and *S*-enantiomers of *Z*-3-methoxymethyl-1-methylpropenylstannane have been allowed to react with the protected erythrose- and threose-derived aldehydes **17-A** and **17-B**. The products are shown below. Indicate the preferred transition structure for each combination.

- 9.18. In the original report of the reaction in Entry 8 of Scheme 9.6, it was found that use of three equivalents of BF_3 led to loss of stereoselectivity, but not yield.

Product Composition

Equiv BF_3	Total Yield	<i>anti</i> anti-Felkin	<i>anti</i> Felkin	<i>syn</i> Felkin	<i>syn</i> anti-Felkin
1	92	94–97	3–4	1	1
2	90	83–91	5–9	1–3	2–5
3	90	41	10	17	32

These results were attributed to a preference for an eight-membered chelated transition structure that was lost in the presence of excess BF_3 because of coordination of a second BF_3 at the ester group. What objections would you raise to this explanation? What alternative would you propose?

- 9.19. The aldehyde **19-A** shows differential stereoselectivity toward the enantiomeric stannanes (*S*)-**19-B** and (*R*)-**19-B**. The former aldehyde gives a single product in high yield, whereas the latter gives a somewhat lower yield and a mixture of two stereoisomers under the same conditions and is a mixture of two stereoisomers. Propose TSs to account for each product and indicate the reasons for the enhanced stereoselectivity of (*S*)-**19-B**.

Reactions Involving Carbocations, Carbenes, and Radicals as Reactive Intermediates

Introduction

Trivalent carbocations, carbanions, and radicals are the most fundamental classes of reactive intermediates. The basic aspects of the structural and reactivity features of these intermediates were introduced in Chapter 3 of Part A. Discussion of carbanion intermediates in synthesis began in Chapter 1 of the present volume and continued through several further chapters. The focus in this chapter is on *electron-deficient reactive intermediates*, including carbocations, carbenes, and carbon-centered radicals. Both carbocations and carbenes have a carbon atom with *six valence electrons* and are therefore *electron-deficient* and *electrophilic* in character, and they have the potential for skeletal rearrangements. We also discuss the use of carbon radicals to form carbon-carbon bonds. Radicals react through homolytic bond-breaking and bond-forming reactions involving intermediates with *seven valence electrons*.

A common feature of these intermediates is that they are of high energy, compared to structures with completely filled valence shells. Their lifetimes are usually very short. Bond formation involving carbocations, carbenes, and radicals often occurs with low activation energies. This is particularly true for addition reactions with alkenes and other systems having π bonds. These reactions replace a π bond with a σ bond and are usually exothermic.

Owing to the low barriers to bond formation, *reactant conformation* often plays a decisive role in the outcome of these reactions. Carbocations, carbenes, and radicals frequently undergo very efficient *intramolecular reactions* that depend on the proximity of the reaction centers. Conversely, because of the short lifetimes of the intermediates, reactions through unfavorable conformations are unusual. Mechanistic analyses and synthetic designs that involve carbocations, carbenes, and radicals must pay particularly close attention to conformational factors.

10.1. Reactions and Rearrangement Involving Carbocation Intermediates

In this section, the emphasis is on carbocation reactions that modify the carbon skeleton, including carbon-carbon bond formation, rearrangements, and fragmentation reactions. The fundamental structural and reactivity characteristics of carbocations toward nucleophilic substitution were explored in Chapter 4 of Part A.

10.1.1. Carbon-Carbon Bond Formation Involving Carbocations

10.1.1.1. Intermolecular Alkylation by Carbocations. The formation of carbon-carbon bonds by electrophilic attack on the π system is a very important reaction in aromatic chemistry, with both Friedel-Crafts alkylation and acylation following this pattern. These reactions are discussed in Chapter 11. There also are useful reactions in which carbon-carbon bond formation results from electrophilic attack by a carbocation on an alkene. The reaction of a carbocation with an alkene to form a new carbon-carbon bond is both kinetically accessible and thermodynamically favorable.

There are, however, serious problems that must be overcome in the application of this reaction to synthesis. The product is a new carbocation that can react further. Repetitive addition to alkene molecules leads to polymerization. Indeed, this is the mechanism of acid-catalyzed polymerization of alkenes. There is also the possibility of rearrangement. A key requirement for adapting the reaction of carbocations with alkenes to the synthesis of small molecules is control of the reactivity of the newly formed carbocation intermediate. Synthetically useful carbocation-alkene reactions require a suitable termination step. We have already encountered one successful strategy in the reaction of alkenyl and allylic silanes and stannanes with electrophilic carbon (see Chapter 9). In those reactions, the silyl or stannyl substituent is eliminated and a stable alkene is formed. The increased reactivity of the silyl- and stannyl-substituted alkenes is also favorable to the synthetic utility of carbocation-alkene reactions because the reactants are more nucleophilic than the product alkenes.

Silyl enol ethers and silyl ketene acetals also offer both enhanced reactivity and a favorable termination step. Electrophilic attack is followed by desilylation to give an α -substituted carbonyl compound. The carbocations can be generated from tertiary chlorides and a Lewis acid, such as TiCl_4 . This reaction provides a method for introducing tertiary alkyl groups α to a carbonyl, a transformation that cannot be achieved by base-catalyzed alkylation because of the strong tendency for tertiary halides to undergo elimination.

Secondary benzylic bromides, allylic bromides, and α -chloro ethers can undergo analogous reactions using ZnBr_2 as the catalyst.² Primary iodides react with silyl ketene acetals in the presence of AgO_2CCF_3 .³

Alkylations via an allylic cation have been observed using LiClO_4 to promote ionization.⁴

These reactions provide examples of intermolecular carbocation alkylations. Despite the feasibility of this type of reaction, the requirements for good yields are stringent and the number of its synthetic applications is limited.

10.1.1.2. Polyene Cyclization. Perhaps the most synthetically useful of the carbocation alkylation reactions is the cyclization of polyenes having two or more double bonds positioned in such a way that successive bond-forming steps can occur. This process, called *polyene cyclization*, has proven to be an effective way of making polycyclic compounds containing six-membered and, in some cases, five-membered rings. The reaction proceeds through an electrophilic attack and requires that the double bonds that participate in the cyclization be properly positioned. For example, compound **1** is converted quantitatively to **2** on treatment with formic acid. The reaction is initiated by protonation and ionization of the allylic alcohol and is terminated by nucleophilic capture of the cyclized secondary carbocation.

Ref. 5

More extended polyenes can cyclize to tricyclic systems.

Ref. 6

These cyclizations are usually highly stereoselective, with the stereochemical outcome being determined by the reactant conformation.⁷ The stereochemistry of the products in the decalin system can be predicted by assuming that cyclization occurs through conformations that resemble chair cyclohexane rings. The stereochemistry at ring junctures is that resulting from *anti* attack at the participating double bonds.

To be of maximum synthetic value, the generation of the cationic site that initiates cyclization must involve mild reaction conditions. Formic acid and stannic chloride are effective reagents for cyclization of polyunsaturated allylic alcohols. Acetals generate oxonium ions in acidic solution and can also be used to initiate the cyclization of polyenes.⁸

⁸ A van der Gen, K. Wiedhaup, J. J. Swoboda, H. C. Dunathan, and W. S. Johnson, *J. Am. Chem. Soc.*, **95**, 2656 (1973).

Another significant method for generating the electrophilic site is acid-catalyzed epoxide ring opening.⁹ Lewis acids such as BF_3 , SnCl_4 , CH_3AlCl_2 , or $\text{TiCl}_3(\text{O}-i\text{-Pr})$ can be used,¹⁰ as illustrated by Entries 4 to 7 in Scheme 10.1.

Mercuric ion is capable of inducing cyclization of polyenes.

Ref. 11

The particular example shown also has a special mechanism for stabilization of the cyclized carbocation. The adjacent acetoxy group is captured to form a stabilized dioxanylium cation. After reductive demercuration (see Section 4.1.3) and hydrolysis, a diol is isolated.

As the intermediate formed in a polyene cyclization is a carbocation, the isolated product is often found to be a mixture of closely related compounds resulting from competing modes of reaction. The products result from capture of the carbocation by solvent or other nucleophile or by deprotonation to form an alkene. Polyene cyclizations can be carried out on reactants that have structural features that facilitate transformation of the carbocation to a stable product. Allylic silanes, for example, are stabilized by desilylation.¹²

The incorporation of silyl substituents not only provides for specific reaction products but can also improve the effectiveness of polyene cyclization. For example, although cyclization of **2a** gave a mixture containing at least 17 products, the allylic silane **2b** gave a 79% yield of a 1:1 mixture of stereoisomers.¹³ This is presumably due to the enhanced reactivity and selectivity of the allylic silane.

¹³ P. V. Fish, *Tetrahedron Lett.*, **35**, 7181 (1994).

The efficiency of cyclization can also be affected by stereoelectronic factors. For example, there is a significant difference in the efficiency of the cyclization of the *Z*- and *E*-isomers of **3**. Only the *Z*-isomer presents an optimal alignment for electronic stabilization.¹⁴ These effects of the terminating substituent point to considerable concerted character for the cyclizations.

When a cyclization sequence is terminated by an alkyne, vinyl cations are formed. Capture of water leads to formation of a ketone.¹⁵

Use of chiral acetals can result in enantioselective cyclization.¹⁶

Polyene cyclizations are of substantial value in the synthesis of polycyclic terpene natural products. These syntheses resemble the processes by which the polycyclic compounds are assembled in nature. The most dramatic example of biosynthesis of a polycyclic skeleton from a polyene intermediate is the conversion of squalene oxide to the steroid lanosterol. In the biological reaction, an enzyme not only induces the cationic cyclization but also holds the substrate in a conformation corresponding to stereochemistry of the polycyclic product.¹⁷ In this case, the cyclization is terminated by a series of rearrangements.

Scheme 10.1 gives some representative examples of laboratory syntheses involving polyene cyclization. The cyclization in Entry 1 is done in anhydrous formic acid and involves the formation of a symmetric tertiary allylic carbocation. The cyclization forms a six-membered ring by attack at the terminal carbon of the vinyl group. The bicyclic cation is captured as the formate ester. Entry 2 also involves initiation by a symmetric allylic cation. In this case, the triene unit cyclizes to a tricyclic ring system. Entry 3 results in the formation of the steroidal skeleton with termination by capture of the alkynyl group and formation of a ketone. The cyclization in Entry 4 is initiated by epoxide opening.

Entries 5 and 6 also involve epoxide ring opening. In Entry 5 the cyclization is terminated by electrophilic substitution on the highly reactive furan ring. In Entry 6 a silyl enol ether terminates the cyclization sequence, leading to the formation of a ketone. Entry 7 incorporates two special features. The terminal propargylic silane generates an allene. The fluoro substituent was found to promote the formation of the six-membered D ring by directing the regiochemistry of formation of the C(8)–C(14) bond. After the cyclization, the five-membered A ring was expanded to a six-membered ring by oxidative cleavage and aldol condensation. The final product of this synthesis was β -amyrin. Entry 8 also led to the formation of β -amyrin and was done using the enantiomerically pure epoxide.

10.1.1.3. Ene and Carbonyl-Ene Reactions. Certain double bonds undergo electrophilic addition reactions with alkenes in which an allylic hydrogen is transferred to the reactant. This process is called the *ene reaction* and the electrophile is known as an *enophile*.¹⁸ When a carbonyl group serves as the enophile, the reaction is called a *carbonyl-ene reaction* and leads to β,γ -unsaturated alcohols. The reaction is also called the *Prins reaction*.

A variety of double bonds give reactions corresponding to the pattern of the ene reaction. Those that have been studied from a mechanistic and synthetic perspective include alkenes, aldehydes and ketones, imines and iminium ions, triazoline-2,5-diones, nitroso compounds, and singlet oxygen, $^1\text{O}=\text{O}$. After a mechanistic overview of the reaction, we concentrate on the carbon-carbon bond-forming reactions. The important and well-studied reaction with $^1\text{O}=\text{O}$ is discussed in Section 12.3.2.

The concerted mechanism shown above is allowed by the Woodward-Hoffmann rules. The TS involves the π electrons of the alkene and enophile and the σ electrons of the allylic C–H bond. The reaction is classified as a $[\pi 2 + \pi 2 + \sigma 2]$ and either an FMO or basis set orbital array indicates an allowed concerted process.

Because the enophiles are normally the electrophilic reagent, their reactivity increases with addition of EWG substituents. Ene reactions between unsubstituted alkenes have high-energy barriers, but compounds such as acrylate or propynoate esters

¹⁸. For reviews of the ene reaction, see H. M. R. Hoffmann, *Angew. Chem. Int. Ed. Engl.*, **8**, 556 (1969); W. Oppolzer, *Pure Appl. Chem.*, **53**, 1181 (1981); K. Mikami and M. Shimizu, *Chem. Rev.*, **92**, 1020 (1992).

or, especially, maleic anhydride are more reactive. Similarly, for carbonyl compounds, glyoxylate, oxomalonate, and dioxosuccinate esters are among the typical reactants under thermal conditions.

Mechanistic studies have been designed to determine if the concerted cyclic TS provides a good representation of the reaction. A systematic study of all the *E*- and *Z*-decene isomers with maleic anhydride showed that the stereochemistry of the reaction could be accounted for by a concerted cyclic mechanism.¹⁹ The reaction is only moderately sensitive to electronic effects or solvent polarity. The ρ value for reaction of diethyl oxomalonate with a series of 1-arylcyclopentenes is -1.2 , which would indicate that there is little charge development in the TS.²⁰ The reaction shows a primary kinetic isotope effect indicative of C–H bond breaking in the rate-determining step.²¹ There is good agreement between measured isotope effects and those calculated on the basis of TS structure.²² These observations are consistent with a concerted process.

The carbonyl-ene reaction is strongly catalyzed by Lewis acids,²³ such as BF_3 , SnCl_4 , and $(\text{CH}_3)_2\text{AlCl}$.^{24,25} Coordination of a Lewis acid at the carbonyl group increases its electrophilicity and allows reaction to occur at or below room temperature. The reaction becomes much more polar under Lewis acid catalysis and is more sensitive to solvent polarity²⁶ and substituent effects. For example, the ρ for 1-arylcyclopentenes with diethyl oxomalonate goes from -1.2 for the thermal reaction to -3.9 for a SnCl_4 -catalyzed reaction. Mechanistic analysis of Lewis acid-catalyzed reactions indicates they are electrophilic substitution processes. At one mechanistic extreme, this might be a concerted reaction. At the other extreme, the reaction could involve formation of a carbocation. In synthetic practice, the reaction is often carried out using Lewis acid catalysts and probably is a stepwise process.

The experimental isotope effects have been measured for the reaction of 2-methylbutene with formaldehyde with diethylaluminum chloride as the catalyst,²⁷ and are consistent with a stepwise mechanism or a concerted mechanism with a large degree of bond formation at the TS. B3LYP/6-31G* computations using H⁺ as the Lewis acid favored a stepwise mechanism.

The best carbonyl components for these reactions are highly electrophilic compounds such as glyoxylate, pyruvate, and oxomalonate esters, as well as chlorinated and fluorinated aldehydes. Most synthetic applications of the carbonyl-ene reaction utilize Lewis acids. Although such reactions may be stepwise in character, the stereochemical outcome is often consistent with a cyclic TS. It was found, for example, that steric effects of trimethylsilyl groups provide a strong stereochemical influence.²⁸

These results are consistent with two competing TSs differing in the facial orientation of the glyoxylate ester group. When X=H, the interaction with the ester group is small and the R^Z-ester interaction controls the stereochemistry. When the silyl group is present, there is a strong preference for TS A, which avoids interaction of the silyl group with the ester substituents.

The mechanisms of simple ene reactions, such as those involving propene with ethene and formaldehyde, have been explored computationally. Concerted mechanisms and E_a values in general agreement with experiment are found using B3LYP/6-31G*,²⁹ MP2/6-31G*,³⁰ and MP4/6-31G*³¹ computations. Yamanaka and Mikami used HF/6-31G* computations to compare the TS for ene reactions of propene with ethene and formaldehyde, and also for $SnCl_4$ - and $AlCl_3$ -catalyzed reactions with methyl glyoxylate.³² The TS geometries and NPA charges are given in Figure 10.1. The ethene and formaldehyde TSs are rather similar, with the transferring hydrogen being positive in character, more so with formaldehyde than ethene. The catalyzed reactions are much more asynchronous, with C–C bond formation quite advanced. The two catalyzed reaction TSs correlate nicely with the observed stereoselectivity of the reaction. The stereochemistry of the 2-butene-methyl glyoxylate reaction shows a strong dependence on the Lewis acid that is used. The $SnCl_4$ -catalyzed reaction gives the *anti* product via an *exo* TS, whereas $AlCl_3$ gives the *syn* product via an *endo* TS. The glyoxylate is chelated with $SnCl_4$, but not with $AlCl_3$, which leads to a difference in the orientation

Fig. 10.1. Minimum-energy transition structures for ene reactions: (a) propene and ethene; (b) propene and formaldehyde; (c) butene and methyl glyoxylate- $SnCl_4$; (d) butene and methyl glyoxylate- $AlCl_3$. Reproduced from *Helv. Chim. Acta*, **85**, 4264 (2002), by permission of Wiley-VCH.

of the unshared electrons on the ester oxygen. The *exo* TS is believed to be favored by an electrostatic interaction between the oxygen and C(4).

Despite the cyclic character of these TSs, both the bond distances and charge distribution are characteristic of a high degree of charge separation, with the butenyl fragment assuming the character of an allylic carbocation.

Visual models, additional information and exercises on the Carbonyl-Ene Reaction can be found in the Digital Resource available at: Springer.com/carey-sundberg.

Examples of catalyst control of stereoselectivity have been encountered in the course of the use of the ene reaction to elaborate a side chain on the steroid nucleus. The steroid **4** gave stereoisomeric products, depending on the catalysts and specific aldehyde that were used.³³ This is attributed to the presence of a chelated structure in the case of the SnCl_4 catalyst.

³³. K. Mikami, H. Kishino, and T.-P. Loh, *J. Chem. Soc., Chem. Commun.*, 495 (1994).

The stereoselectivity of the $(\text{CH}_3)_2\text{AlCl}$ -catalyzed reaction has also been found to be sensitive to the steric bulk of the aldehyde.³⁴

The use of Lewis acid catalysts greatly expands the synthetic utility of the carbonyl-ene reaction. Aromatic aldehydes and acrolein undergo the ene reaction with activated alkenes such as enol ethers in the presence of $\text{Yb}(\text{fod})_3$.³⁵ $\text{Sc}(\text{O}_3\text{SCF}_3)_3$ has also been used to catalyze carbonyl-ene reactions.³⁶

Among the more effective conditions for reaction of formaldehyde with α -methylstyrenes is BF_3 in combination with 4A molecular sieves.³⁷

The function of the molecular sieves in this case is believed to be as a base that sequesters the protons, which otherwise would promote a variety of side reactions. With chiral catalysts, the carbonyl ene reaction becomes enantioselective. Among the successful catalysts are diisopropoxyTi(IV)BINOL and copper-BOX complexes.

Ref. 41

The enantioselectivity of the BINOL-Ti(IV)-catalyzed reactions can be interpreted in terms of several fundamental structural principles.⁴² The aldehyde is coordinated to Ti through an apical position and there is also a O–HC=O hydrogen bond involving the formyl group. The most sterically favored approach of the alkene toward the complexed aldehyde then leads to the observed product. Figure 10.2 shows a representation of the complexed aldehyde and the TS structure for the reaction.

Most carbonyl-ene reactions used in synthesis are intramolecular and can be carried out under either thermal or catalyzed conditions,⁴³ but generally Lewis acids are used. Stannic chloride catalyzes cyclization of the unsaturated aldehyde **5**.

The cyclization of the α -ketoester **6** can be effected by $\text{Mg}(\text{ClO}_4)_2$, $\text{Yb}(\text{OTf})_3$, $\text{Cu}(\text{OTf})_2$, or $\text{Sc}(\text{OTf})_3$.⁴⁵ The reaction exhibits a 20:1 preference for formation of the *trans*-2-(1-methylpropenyl) isomer. The reaction can be conducted with greater than 90% e.e. using $\text{Cu}(\text{OTf})_2$ or $\text{Sc}(\text{OTf})_3$ with the *t*-Bu-BOX ligand.

As an example of a thermal reaction, **7** cyclizes at 180°C. The reaction is stereoselective and the two stereoisomers can be formed from competing cyclic TSs.⁴⁶

Carbonyl-ene reactions can be carried out in combination with other kinds of reactions. Mixed acetate acetals of γ,δ -enols, which can be prepared from the corresponding acetate esters, undergo cyclization with nucleophilic capture. When SnBr_4 is used for cyclization, the 4-substituent is bromine, whereas BF_3 in acetic acid gives acetates.⁴⁷

The reaction stereochemistry is consistent with a cyclic TS.

A tandem combination initiated by a Mukaiyama reaction generates an oxonium ion that cyclizes to give a tetrahydropyran rings.⁴⁸

This reaction has been used in coupling two fragments in a synthesis of leucascandrolide, a cytotoxic substance isolated from a sponge.⁴⁹

A tandem Sakurai-carbonyl-ene sequence was used to create a tricyclic skeleton in the synthesis of a steroidal structure.⁵⁰

Section 10.1.2.2 describes another tandem reaction sequence involving a carbonyl-ene reaction.

Scheme 10.2 gives some examples of ene and carbonyl-ene reactions. Entries 1 and 2 are thermal ene reactions. Entries 3 to 7 are intermolecular ene and carbonyl-ene reactions involving Lewis acid catalysts. Entry 3 is interesting in that it exhibits a significant preference for the terminal double bond. Entry 4 demonstrates the reactivity of methyl propynoate as an enophile. Nonterminal alkenes tend to give cyclobutenes with this reagent combination. The reaction in Entry 5 uses an acetal as the reactant, with an oxonium ion being the electrophilic intermediate.

Entry 6 uses diisopropoxytitanium with racemic BINOL as the catalyst. Entry 7 shows the use of $(CH_3)_2AlCl$ with a highly substituted aromatic aldehyde. The product

was used in syntheses of derivatives of robustadiol, which are natural products from *Eucalyptus* that have antimalarial activity.

Entries 8 to 15 are examples of intramolecular reactions. Entry 8 involves two unactivated double bonds and was carried out at a temperature of 280°C. The product was a mixture of epimers at the ester site but the methyl group and cyclohexenyl double bond are *cis*, which indicates that the reaction occurred entirely through an *endo* TS.

The reaction in Entry 9 was completely stereospecific. The corresponding *E*-isomer gave mainly the *cis* isomer. These results are consistent with a cyclic TS for the hydrogen transfer.

The stereoselectivity of the reaction in Entry 10 is also consistent with a TS in which the hydrogen is transferred through a chairlike TS.

Entry 11 illustrates the facility of a $\text{Sc}(\text{OTf})_3$ -mediated reaction. The catalyst in Entry 12 is a hindered *bis*-phenoxyaluminum compound. The proton removal

in Entry 12 is highly stereoselective, giving rise to a single exocyclic double-bond isomer. This stereochemistry is consistent with a TS that incorporates the six-membered hydrogen transfer TS into a bicyclic framework.

Entries 13 to 15 are examples of high-yield cyclizations of aldehydes effected by CH_3AlCl_2 .

Section D of Scheme 10.2 shows some enantioselective reactions. Entry 16 illustrates the enantioselective reaction of methyl glyoxylate with a simple alkene. The catalyst is a dioxido-bridged dimer of $\text{Ti}(\text{BINOL})$ prepared azeotropically from BINOL and $\text{TiCl}_2(\text{O}-i\text{-Pr})_2$. Entry 17 also uses a $\text{Ti}(\text{BINOL})$ catalyst. The methylenedihydrofuran substrate is highly reactive owing to the donor effect of the vinyl ether and the stabilization provided by formation of the aromatic furan ring. Entry 18 shows the use of a $\text{Cu}\text{-BOX}$ catalysts to achieve a highly enantioselective reaction between isobutene and ethyl glyoxylate. The reaction in Entry 19 was done with a $(i\text{-PrO})_2\text{TiCl}_2\text{-(R)-BINOL}$ and the product had an e.e. of 89%.

10.1.1.4. Reactions with Acylium Ions. Alkenes react with acyl halides or acid anhydrides in the presence of a Lewis acid catalyst to give β,γ -unsaturated ketones. The reactions generally work better with cyclic than acyclic alkenes.

It has been suggested that the kinetic preference for formation of β,γ -unsaturated ketones results from an intramolecular deprotonation, as shown in the mechanism above.⁵¹ The carbonyl-ene and alkene acylation reactions have several similarities. Both reactions occur most effectively in intramolecular circumstances and provide a useful method for ring closure. Although both reactions appear to occur through highly polarized TSs, there is a strong tendency toward specificity in the proton abstraction step. This specificity and other similarities in the reaction are consistent with a cyclic formulation of the mechanism.

A variety of reaction conditions have been examined for acylation of alkenes by acyl chlorides. With the use of Lewis acid catalysts, reaction typically occurs

⁵¹. P. Beak and K. R. Berger, *J. Am. Chem. Soc.*, **102**, 3848 (1980).

to give both β,γ -enones and β -haloketones.⁵² One of the more effective catalysts is ethylaluminum dichloride.⁵³

Zinc chloride also gives good results, especially with cyclic alkenes.⁵¹

A similar reaction occurs between alkenes and acylium ions, as in the reaction between 2-methylpropene, and the acetylium ion leads regiospecifically to β,γ -enones.⁵⁴ A concerted mechanism has been suggested to account for this regiochemical preference.

Highly reactive mixed anhydrides can also promote acylation. Phenylacetic acid reacts with alkenes to give 2-tetralones in TFAA- H_3PO_4 .⁵⁵ This reaction involves an intramolecular Friedel-Crafts alkylation subsequent to the acylation.

The acylation reaction has been most synthetically useful in intramolecular reactions. The following examples are illustrative.

Ref. 56

Ref. 57

Several successful cyclizations of quite complex structures were achieved using polyphosphoric acid trimethylsilyl ester, a viscous material that contains reactive anhydrides of phosphoric acid.⁵⁸ Presumably the reactive acylating agent is a mixed phosphoric anhydride of the carboxylic acid.

Ref. 59

10.1.2. Rearrangement of Carbocations

Carbocations, as we learned in Chapter 4 of Part A, can readily rearrange to more stable isomers. To be useful in synthesis, such reactions must be controlled and predictable. This goal can be achieved on the basis of substituent effects and stereoelectronic factors. Among the most important rearrangements in synthesis are those directed by oxygen substituents, which can provide predictable outcomes on the basis of electronic and stereoelectronic factors.

10.1.2.1. Pinacol Rearrangement. Carbocations can be stabilized by the migration of hydrogen, alkyl, alkenyl, or aryl groups, and, occasionally, even functional groups can migrate. A mechanistic discussion of these reactions is given in Section 4.4.4 of Part A. Reactions involving carbocation rearrangements can be complicated by the existence of competing rearrangement pathways. Rearrangements can be highly selective and, therefore, reliable synthetic reactions when the structural situation is such as to strongly favor a particular reaction path. One example is the reaction of carbocations having a hydroxy group on an adjacent carbon, which leads to the formation of a carbonyl group.

A reaction that follows this pattern is the acid-catalyzed conversion of diols to ketones, which is known as the *pinacol rearrangement*.⁶⁰ The classic example of this reaction is the conversion of 2,3-dimethylbutane-2,3-diol (pinacol) to methyl *t*-butyl ketone (pinacolone).⁶¹

⁵⁸. K. Yamamoto and H. Watanabe, *Chem. Lett.*, 1225 (1982).

⁵⁹. W. Li and P. L. Fuchs, *Org. Lett.*, **5**, 4061 (2003).

⁶⁰. C. J. Collins, *Q. Rev.*, **14**, 357 (1960).

⁶¹. G. A. Hill and E. W. Florsdorf, *Org. Synth.*, **I**, 451 (1932).

The acid-catalyzed mechanism involves carbocation formation and substituent migration assisted by the hydroxy group.

Under acidic conditions, the more easily ionized C–O bond generates the carbocation, and migration of one of the groups from the adjacent carbon ensues. Both stereochemistry and “migratory aptitude” are factors in determining the extent of migration of the different groups. The issue of the electronic component in migratory aptitude has been examined by calculating (MP2/6-31G*) the relative energy for several common groups in a prototypical TS for migration. The order is vinyl > cyclopropyl > alkynyl > methyl ~ hydrogen.⁶² The tendency for migration of alkenyl groups is further enhanced by ERG substituents and selective migration of trimethylsilyl-substituted groups has been exploited in pinacol rearrangements.⁶³ In the example shown, the triethylsilane serves to reduce the intermediate silyloxonium ion and generate a primary alcohol.

Another method for achieving selective pinacol rearrangement involves synthesis of a glycol monosulfonate ester. These compounds rearrange under the influence of base.

Rearrangements of monosulfonates permit greater control over the course of the rearrangement because ionization occurs only at the sulfonated alcohol. These reactions have been of value in the synthesis of ring systems, especially terpenes, as illustrated by Entries 3 and 4 in Scheme 10.3.

In cyclic systems that enforce structural rigidity or conformational bias, the course of the rearrangement is controlled by stereoelectronic factors. The carbon substituent that is *anti* to the leaving group is the one that undergoes migration. In cyclic systems such as **8**, for example, selective migration of the ring fusion bond occurs because

⁶². K. Nakamura and Y. Osamura, *J. Am. Chem. Soc.*, **115**, 9112 (1993).

⁶³. K. Suzuki, T. Ohkuma, and G. Tsuchihashi, *Tetrahedron Lett.*, **26**, 861 (1985); K. Suzuki, M. Shimazaki, and G. Tsuchihashi, *Tetrahedron Lett.*, **27**, 6233 (1986); M. Shimazaki, M. Morimoto, and K. Suzuki, *Tetrahedron Lett.*, **31**, 3335 (1990).

of this stereoelectronic effect. In both cyclic and acyclic systems, the rearrangement takes place with *retention of configuration* at the migration terminus.

Ref. 64

Similarly, **10** gives **11** by antiperiplanar migration.

Ref. 65

Rearrangement of diol monosulfonates can also be done using Lewis acids. These conditions lead to *inversion of configuration* at the migration terminus, as would be implied by a concerted mechanism.⁶⁶

Triethylaluminum is also effective in catalyzing rearrangement of monosulfonate with high stereospecificity. The reactions are believed to proceed through a cyclic TS.⁶⁷

The reactants can be prepared by chelation-controlled addition of organometallic reagents to α -(1-ethoxyethoxy)methyl ketones. Selective sulfonylation occurs at the

less hindered secondary hydroxy group. The rearranged ketones were obtained in greater than 99% e.e.

A related method was applied in the course of synthesis of a precursor of a macrolide antibiotic, protomycinolide IV. The migrating group was an α -trimethylsilylalkenyl group.⁶⁸ In this procedure, the DiBALH first reduces the ketone and then, after rearrangement, reduces the aldehyde to a primary alcohol.

Stereospecific ring expansion can be done by taking advantage of the hydroxy-directed epoxidation and SnCl_4 -mediated rearrangement of 1-hydroxycycloalkyl epoxides.⁶⁹

The overall transformation of this sequence corresponds to the aldol addition of an aldehyde with a cyclic ketone. The actual aldol addition frequently proceeds with low stereocontrol, so this sequence constitutes a method for stereoselective synthesis of the aldol adducts. The reaction has been done with several Lewis acids, including SnCl_4 , BF_3 , and $\text{Ti}(\text{O}-i\text{-Pr})_3\text{Cl}$.

10.1.2.2. Pinacol Rearrangement in Tandem with the Carbonyl-Ene Reaction. Overman and co-workers have developed protocols in which pinacol rearrangement

⁶⁸. K. Suzuki, K. Tomooka, E. Katayama, T. Matsumoto, and G. Tsuchihashi, *J. Am. Chem. Soc.*, **108**, 5221 (1986).

⁶⁹. S. W. Baldwin, P. Chen, N. Nikolic, and D. C. Weinseimer, *Org. Lett.*, **2**, 1193 (2000); C. M. Marson, A. Khan, R. A. Porter, and A. J. A. Cobb, *Tetrahedron Lett.*, **43**, 6637 (2002).

occurs in tandem with a carbonyl-ene reaction and results in both a ring closure and ring expansion.⁷⁰

These reactions appear to proceed through the sequence $\text{C} \rightarrow \text{D} \rightarrow \text{E}$. When the seven-membered analog ($n = 3$) reacts, two products are formed. The more flexible seven-membered ring accommodates the competing sequence. $\text{F} \rightarrow \text{G} \rightarrow \text{H}$.

The carbonyl-ene-pinacol sequence has also been observed in reactions leading to the formation of tetrahydrofurans.⁷¹

The reaction has been developed for the synthesis of both oxygen heterocycles and carbocyclic compounds.⁷²

Ref. 73

Ref. 74

These reactions can also be adapted to carbocyclic ring formation and expansion.

Ref. 75

Ref. 76

Scheme 10.3 gives some examples of pinacol and related rearrangements. Entry 1 is a rearrangement done under strongly acidic conditions. The selectivity leading to ring expansion results from the preferential ionization of the diphenylcarbinol group. Entry 2, a preparation of 2-indanone, involves selective ionization at the benzylic alcohol, followed by a hydride shift.

Entries 3 and 4 are examples of stereospecific *anti* migrations governed by the stereochemistry of the sulfonate leaving group. These transformations are parts of synthetic schemes that use available terpene starting materials for synthesis of more complex natural products. The ring expansion in Entry 5 was used to form an eight-membered ring found in certain diterpenes. This highly efficient and selective rearrangement

presumably proceeds with participation of the adjacent oxygen, which accounts for the specific migration of bond *a* over bond *b*.

Entry 6 illustrates a significant regioselectivity in that two tertiary alcohol groups are present in the reactant. This reaction is thought to involve a cyclic orthoester. The preferred rupture of the C—O bond distal to the *p*-nitrobenzyloxy group is likely due to the dipolar effect of the C—O bond on ionization. No migration of the oxy-substituted ring is observed, indicating that the *p*-nitrobenzyloxy group minimizes any potential electron donation by the oxygen.

Entry 7 involves formation and ionization of a secondary allylic sulfonate and migration of a dienyl group.

Entry 8 involves a migration initiated by epoxide ring opening. This reaction involves migration of a vinyl substituent. Entry 9 is a stereospecific migration of the aryl group. The DiBAIH both promotes the rearrangement and reduces the product aldehyde.

10.1.2.3. Rearrangements Involving Diazonium Ions. Aminomethyl carbinols yield ketones when treated with nitrous acid. The reaction proceeds by formation and rearrangement of diazonium ions. The diazotization reaction generates the same type of β -hydroxycarbocation that is involved in the pinacol rearrangement.

This reaction has been used to form ring-expanded cyclic ketones, a procedure known as the *Tiffeneau-Demjanov reaction*.⁷⁷

Ref. 78

The reaction of ketones with diazomethane sometimes leads to a ring-expanded ketone in synthetically useful yields.⁷⁹ The reaction occurs by addition of the diazomethane, followed by elimination of nitrogen and migration.

The rearrangement proceeds via essentially the same intermediate that is involved in the Tiffeneau-Demjanov reaction. Since the product is also a ketone, subsequent addition of diazomethane can lead to higher homologs. The best yields are obtained when the starting ketone is substantially more reactive than the product. For this reason, strained ketones work especially well. Higher diazoalkanes can also be used in place of diazomethane. The reaction is found to be accelerated by alcoholic solvents. This effect probably involves the hydroxy group being hydrogen bonded to the carbonyl oxygen and serving as a proton donor in the addition step.⁸⁰

Trimethylaluminum also promotes ring expansion by diazoalkanes.⁸¹

Ketones react with esters of diazoacetic acid in the presence of Lewis acids such as BF_3 and SbCl_5 .⁸²

These reactions involve addition of the diazo ester to an adduct of the carbonyl compound and the Lewis acid. Elimination of nitrogen then triggers migration. Triethyloxonium tetrafluoroborate also effects ring expansion of cyclic ketones by ethyl diazoacetate.⁸³

Scheme 10.4 gives some examples of synthetic applications of rearrangements of diazonium ions. The diazotization rearrangement in Entry 1 was used to assemble the four contiguous stereogenic centers of the oxygenated cyclopentane ring found in prostaglandins. The synthesis started with *cis,cis*-1,3,5-cyclohexanetriol. Entry 2 uses trimethylsilyl cyanide addition, followed by LiAlH_4 reduction to generate the amino alcohol. The minor product in this reaction is formed by competing migration of the bridgehead carbon. The reaction was part of a synthesis of the terpene cedrene. Entry 3 is an example of the use of diazomethane to effect ring expansion of a strained ketone. The reaction was carried out by generating the diazomethane in situ. Entry 4 is an example of BF_3 -mediated addition and rearrangement using ethyl diazoacetate. In Entry 5, the diazo group was generated in situ, and the intramolecular addition-rearrangement occurs at 25°C and under alkaline conditions. In this case there is little selectivity between the two competing migration possibilities.

10.1.3. Related Rearrangements

The subjects of this section are two reactions that do not actually involve carbocation intermediates. They do, however, result in carbon to carbon rearrangements that are structurally similar to the pinacol rearrangement. In both reactions cyclic intermediates are formed, at least under some circumstances. In the *Favorskii rearrangement*, an α -halo ketone rearranges to a carboxylic acid or ester. In the *Ramberg-Backlund reaction*, an α -halo sulfone gives an alkene.

10.1.3.1. The Favorskii Rearrangement. When treated with base, α -halo ketones undergo a skeletal change that is similar to the pinacol rearrangement. The most commonly used bases are alkoxide ions, which lead to esters as the reaction products. This reaction is known as the *Favorskii rearrangement*.⁸⁴

There is also a mechanism that can operate in the absence of an acidic α -hydrogen. This process, called the *semibenzilic rearrangement*, is closely related to the pinacol rearrangement. A tetrahedral intermediate is formed by nucleophilic addition to the carbonyl group and the halide serves as the leaving group.

The net structural change is the same for both mechanisms. The energy requirements of the cyclopropanone and semibenzilic mechanism may be fairly closely balanced.⁸⁷ Cases of operation of the semibenzilic mechanism have been reported even for compounds having a hydrogen available for enolization.⁸⁸ Among the evidence that the cyclopropanone mechanism operates is the demonstration that a symmetrical intermediate is involved. The isomeric chloro ketones **12** and **13**, for example, lead to the same ester.

Ref. 37

The occurrence of a symmetrical intermediate has also been demonstrated by ^{14}C labeling in the case of α -chlorocyclohexanone.⁸⁹

* = ^{14}C label

Numbers refer to percentage of label at each carbon.

When the two carbonyl substituents are identical, either the cyclopropanone or the dipolar equivalent is symmetric. As the α - and α' -carbons are electronically similar (identical in symmetrical cases) in these intermediates, the structure of the ester product

cannot be predicted directly from the structure of the reacting haloketone. Instead, the identity of the product is governed by the direction of ring opening of the cyclopropanone intermediate. The dominant mode of ring opening is expected to be the one that forms the more stable of the two possible ester enolates. For this reason, a phenyl substituent favors breaking the bond to the substituted carbon, but an alkyl group directs the cleavage to the less-substituted carbon.⁹⁰ That both **12** and **13** above give the same ester, **14**, is illustrative of the directing effect that the phenyl group has on the ring-opening step.

Scheme 10.5 gives some examples of Favorskii rearrangements. Entries 1 and 2 are examples of classical reaction conditions, the latter involving a ring contraction. Entry 3 is an interesting ring contraction-elimination. The reaction was shown to be highly stereospecific, with the *cis*-dibromide giving exclusively the *E*-double bond, whereas the *trans*-dibromide gave mainly the *Z*-double bond. Entry 4 is a ring contraction leading to the formation of an interesting strained-cage hydrocarbon skeleton. Entry 5 is a step in the synthesis of the natural analgesic epibatidine.

10.1.3.2. The Ramberg-Backlund Reaction. α -Halosulfones undergo a related rearrangement known as the *Ramberg-Backlund reaction*.⁹¹ The carbanion formed by deprotonation gives an unstable thiirane dioxide that decomposes with elimination of sulfur dioxide. This elimination step is considered to be a concerted cycloelimination.

The overall transformation is the conversion of the carbon-sulfur bonds to a carbon-carbon double bond. The original procedure involved halogenation of a sulfide, followed by oxidation to the sulfone. Recently, the preferred method has reversed the order of the steps. After the oxidation, which is normally done with a peroxy acid, halogenation is done under basic conditions by use of CBr_2F_2 or related polyhalomethanes for the halogen transfer step.⁹² This method was used, for example, to synthesize 1,8-diphenyl-1,3,5,7-octatetraene.

The Ramberg-Bäcklund reaction has found several applications. Owing to the concerted nature of the elimination, it can be applied to both small and large rings containing a double bond.

Ref. 93

⁹³ L. A. Paquette, J. C. Philips, and R. E. Wingard, Jr., *J. Am. Chem. Soc.*, **93**, 4516 (1971).

Ref. 94

A recently developed application of the Ramberg-Bäcklund reaction is the synthesis of C-glycosides. The required thioethers can be prepared easily by exchange with a thiol. The application of the Ramberg-Bäcklund conditions then leads to an exocyclic vinyl ether that can be reduced to the C-nucleoside.⁹⁵ Entries 3 and 4 in Scheme 10.6 are examples. The vinyl ether group can also be transformed in other ways. In the synthesis of partial structures of the antibiotic altromycin, the vinyl ether product was subjected to diastereoselective hydroboration.

Scheme 10.6 gives some examples of the Ramberg-Bäcklund reaction. Entry 1 was used to prepare analogs of the antimalarial compound artemisinin for biological evaluation. The reaction in Entry 2 was used to install the side chain in a synthesis of the chrysomycin type of antibiotic. Entries 3 and 4 are examples of formation of C-glycosides.

10.1.4. Fragmentation Reactions

The classification *fragmentation* applies to reactions in which a carbon-carbon bond is broken. One structural feature that permits fragmentation to occur readily is the presence of a carbon that can accommodate carbocationic character β to a developing electron deficiency. This type of reaction, known as the *Grob fragmentation*, occurs particularly readily when the γ -atom is a heteroatom, such as nitrogen or oxygen, that has an unshared electron pair that can stabilize the new cationic center.⁹⁶

The fragmentation can be concerted or stepwise. The concerted mechanism is restricted to molecular geometry that is appropriate for continuous overlap of the participating

orbitals. An example is the solvolysis of 4-chloropiperidine, which is faster than the solvolysis of chlorocyclohexane and occurs by fragmentation of the C(2)–C(3) bond.⁹⁷

1,3-Diols or β -hydroxy ethers are particularly useful substrates for fragmentation. If the diol or hydroxy ether is converted to a monotosylate, the remaining oxy group can promote fragmentation.

⁹⁷ R. D'Arcy, C. A. Grob, T. Kaffenberger, and V. Krasnobajew, *Helv. Chim. Acta*, **49**, 185 (1966).

Ref. 98

Similarly, a carbonyl group at the fifth carbon from a leaving group, reacting as the enolate, promotes fragmentation with formation of an enone.⁹⁹ This is a *vinyllogous* analog of the Grob fragmentation.

β -Hydroxyketones are also subject to fragmentation. Lewis acids promote fragmentation of mixed aldol products derived from aromatic aldehydes.¹⁰⁰

The same fragmentation is effected by $\text{Yb}(\text{OTf})_3$ on heating with the aldol adduct in the absence of solvent.¹⁰¹

Organoboranes undergo fragmentation if a good leaving group is present on the δ -carbon.¹⁰² The reactive intermediate is the tetrahedral borate formed by addition of hydroxide ion at boron.

¹⁰³. J. A. Marshall and G. L. Bundy, *J. Am. Chem. Soc.*, **88**, 4291 (1966).

The usual synthetic objective of a fragmentation reaction is the construction of a medium-sized ring from a fused ring system. As the fragmentation reactions are usually concerted stereoselective processes, the stereochemistry is predictable. In 3-hydroxy tosylates, the fragmentation is most favorable for a geometry in which the carbon-carbon bond being broken is in an *anti*-periplanar relationship to the leaving group.¹⁰⁴ Other stereochemical relationships in the molecule are retained during the concerted fragmentation. In the case below, for example, the newly formed double bond has the *E*-configuration.

Fragmentation reactions can also be used to establish stereochemistry of acyclic systems based on stereochemical relationships built into cyclic reactants. In both the examples shown below, the aldehyde group generated by fragmentation was reduced *in situ*.

Ref. 105

Ref. 106

Scheme 10.7 provides some additional examples of fragmentation reactions that have been employed in a synthetic context. Entry 1 was used in the late stages of the synthesis of (\pm)-hinesol, an example of a terpene possessing a spiro[4,5]decane skeleton. The fragmentation provides the spiro ring system with a vinyl side chain. Entry 2 illustrates the formation of a medium ring by fragmentation of a bicyclic system. In this case LiAlH_4 serves as a base and also reduces the carbonyl group in the product, but closely related reactions were carried out with the more usual alkoxide bases. The reaction in Entry 3 was developed during exploration of the

chemistry of the reactant, which is readily available by a Diels-Alder reaction of 1-methoxycyclohexadiene. This acid-catalyzed fragmentation is induced by protonation of the acetyl group.

Entry 4 involves nitrogen participation and formation of an iminium ion that is reduced by NaBH_4 . The reaction in Entry 5 creates an 11-methylenebicyclo[4.3.1]undecen-3-one structure found in a biologically active natural product. Note that this fragmentation creates a bridgehead double bond. Entry 6 involves construction of a portion of the taxol structure. The reaction in Entry 7 is stereospecific, leading to the *E*-double bond.

Entry 8 was used to create the central nine-membered ring system found in the diterpene jatrophatriene. Entry 9 is an example of a boronate fragmentation (see p. 899). Entry 10 illustrates enolate fragmentation. The reaction presumably proceeds

through an extended conformation that aligns the enolate and sulfonate leaving group advantageously and results in an *E*-double bond.

10.2. Reactions Involving Carbenes and Related Intermediates

Carbenes can be included with carbanions, carbocations, and carbon-centered radicals as being among the fundamental intermediates in the reactions of carbon compounds. Carbenes are neutral divalent derivatives of carbon. As would be expected from their electron-deficient nature, most carbenes are highly reactive. Depending upon the mode of generation, a carbene can be formed in either the singlet or the triplet state, no matter which is lower in energy. The two electronic configurations have different geometry and reactivity. A conceptual picture of the bonding in the singlet assumes sp^2 hybridization at carbon, with the two unshared electrons in an sp^2 orbital. The p orbital is unoccupied. The $R-C-R$ angle would be expected to be contracted slightly from 120° because of the electronic repulsions between the unshared electron pair and the electrons in the two bonding σ orbitals. The bonds in a triplet carbene are considered to be formed from sp orbitals with the unpaired electrons being in two equivalent p orbitals. This bonding arrangement predicts a linear structure.

Both theoretical and experimental studies have provided more detailed information about carbene structure. Molecular orbital calculations lead to the prediction of $H-C-H$ angles for methylene of roughly 135° for the triplet and about 105° for the singlet. The triplet is calculated to be about 8 kcal/mol lower in energy than the singlet.¹⁰⁷ Experimental determinations of the geometry of CH_2 accord with the theoretical results. The $H-C-H$ angle of the triplet state, as determined from the ESR spectrum is 125° – 140° . The $H-C-H$ angle of the singlet state is found to be 102° by electronic spectroscopy. The available evidence is consistent with the triplet being the ground state species.

Substituents perturb the relative energies of the singlet and triplet states. In general, alkyl groups resemble hydrogen as a substituent and dialkylcarbenes are ground state

¹⁰⁷. J. F. Harrison, *Acc. Chem. Res.*, **7**, 378 (1974); P. Saxe, H. F. Shaefer, and N. C. Hardy, *J. Phys. Chem.*, **85**, 745 (1981); C. C. Hayden, M. Newmark, K. Shobatake, R. K. Sparks, and Y. T. Lee, *J. Chem. Phys.*, **76**, 3607 (1982); R. K. Lengel and R. N. Zare, *J. Am. Chem. Soc.*, **100**, 739 (1978); C. W. Bauschlicher, Jr., and I. Shavitt, *J. Am. Chem. Soc.*, **100**, 739 (1978); A. R. W. M. Kellar, P. R. Bunker, T. J. Sears, K. M. Evenson, R. Saykally, and S. R. Langhoff, *J. Chem. Phys.*, **79**, 5251 (1983).

triplets. Substituents that act as electron-pair donors stabilize the singlet state more than the triplet state by delocalization of an electron pair into the empty p orbital.¹⁰⁸

The presence of more complex substituent groups complicates the description of carbene structure. Furthermore, since carbenes are high-energy species, structural entities that would be unrealistic for more stable species must be considered. As an example, one set of MO calculations¹⁰⁹ arrives at structure **I** as a better description of carbomethoxycarbene than the conventional structure **J**.

π -Delocalization involving divalent carbon in conjugated cyclic systems has been studied in the interesting species cyclopropenylidene (**K**)¹¹⁰ and cycloheptatrienylidene (**L**).¹¹¹ In these molecules the empty p orbital on the carbene carbon can be part of the aromatic π system and be delocalized over the entire ring. Currently available data indicate that the ground state structures for both **K** and **L** are singlets, but for **L**, the most advanced theoretical calculations indicate that the most stable singlet structure has an electronic configuration in which one of the nonbonded electrons is in the π orbital.¹¹²

There are a number of ways of generating carbenes that will be discussed shortly. In some cases, the reactions involve complexes or precursors of carbenes rather than the carbene per se. For example, carbenes can be generated by α -elimination reactions. Under some circumstances the question arises as to whether the carbene has a finite lifetime, and in some cases a completely free carbene structure is never attained.

When a reaction appears to involve a species that reacts as expected for a carbene but must still be at least partially bound to other atoms, the term *carbenoid* is used. Some carbenelike processes involve transition metal ions. In many of these reactions, the divalent carbene is bound to the metal. Some compounds of this type are stable, whereas others exist only as transient intermediates. In most cases, the reaction involves the metal-bound carbene, rather than a free carbene.

metal-bound carbene

The stability and reactivity of metallocarbenes depends on the degree of back donation from the metal to the carbene. If this is small, the metallocarbenes are highly reactive and electrophilic in character. If back bonding is substantial, the carbon will be less electrophilic, and the reactions are more likely to involve the metal.

dominant electron
distribution in electrophilic
metallo-carbenesdominant electron
distribution in metallo-
carbenes with strong back-bonding

Carbenes and carbenoids can add to double bonds to form cyclopropanes or insert into C–H bonds.

These reactions have *very low activation energies* when the intermediate is a “free” carbene. Intermolecular insertion reactions are inherently nonselective. The course of intramolecular reactions is frequently controlled by the proximity of the reacting groups.¹¹³ Carbene intermediates can also be involved in rearrangement reactions. In the sections that follow we also consider a number of rearrangement reactions that probably do not involve carbene intermediates, but lead to transformations that correspond to those of carbenes.

10.2.1. Reactivity of Carbenes

From the point of view of both synthetic and mechanistic interest, much attention has been focused on the addition reaction between carbenes and alkenes to give cyclopropanes. Characterization of the reactivity of substituted carbenes in addition reactions has emphasized stereochemistry and selectivity. The reactivities of singlet and triplet states are expected to be different. The triplet state is a diradical, and would be expected to exhibit a selectivity similar to free radicals and other species with unpaired electrons. The singlet state, with its unfilled *p* orbital, should be electrophilic and exhibit reactivity patterns similar to other electrophiles. Moreover, a triplet addition

¹¹³ S. D. Burke and P. A. Grieco, *Org. React.*, **26**, 361 (1979).

process must go through a 1,3-diradical intermediate that has two unpaired electrons of the same spin. In contrast, a singlet carbene can go to a cyclopropane in a single concerted step.¹¹⁴ As a result, it was predicted that additions of singlet carbenes would be stereospecific, whereas those of triplet carbenes would not be.¹¹⁵ This expectation has been confirmed and the stereoselectivity of addition reactions with alkenes is used as a test for the involvement of the singlet versus triplet carbene in specific reactions.¹¹⁶

The radical versus electrophilic character of triplet and singlet carbenes also shows up in relative reactivity patterns given in Table 10.1. The relative reactivity of singlet dibromocarbene toward alkenes is more similar to electrophiles (bromination, epoxidation) than to radicals ($\cdot CCl_3$).

Carbene reactivity is strongly affected by substituents.¹¹⁷ Various singlet carbenes have been characterized as nucleophilic, ambiphilic, and electrophilic as shown in Table 10.2. This classification is based on relative reactivity toward a series of both nucleophilic alkenes, such as tetramethylethylene, and electrophilic ones, such as acrylonitrile. The principal structural feature that determines the reactivity of the carbene is the ability of the substituent to act as an electron donor. For example, dimethoxycarbene is devoid of electrophilicity toward alkenes because of electron donation by the methoxy groups.¹¹⁸

SECTION 10.2

Reactions Involving
Carbenes and Related
Intermediates

Absolute rates have been measured for some carbene reactions. The rate of addition of phenylchlorocarbene shows a small dependence on alkene substituents, but as expected for a very reactive species, the range of reactivity is quite narrow.¹¹⁹ The rates are comparable to moderately fast bimolecular addition reactions of radicals (see Part A, Table 11.3).

The rates of phenylchlorocarbene have also been compared with the fluoro and bromo analogs.¹²⁰ The data show slightly decreased rates in the order Br > Cl > F. The alkene reactivity difference is consistent with an electrophilic attack. These reactions have low activation barriers and the reactivity differences are dominated by entropy effects.

¹¹⁹ N. Soundararajan, M. S. Platz, J. E. Jackson, M. P. Doyle, S.-M. Oon, M. J. H. Liu, and S. M. Anand, *J. Am. Chem. Soc.*, **110**, 7143 (1988).

¹²⁰ R. A. Moss, W. Lawrynowicz, N. J. Turro, I. R. Gould, and Y. Cha, *J. Am. Chem. Soc.*, **108**, 7028 (1986).

There is a small dependence on the rate of solvent insertion reactions for saturated hydrocarbons.¹²¹ Benzene is much less reactive.

Absolute rate for solvent insertion by 4-methylphenylchlorocarbene

An HSAB analysis of singlet carbene reactivity based on B3LYP/6-31G* computations has calculated the extent of charge transfer for substituted alkenes,¹²² and the results are summarized in Figure 10.3. The trends are as anticipated for changes in structure of both the carbene and alkene. The charge transfer interactions are consistent with HOMO-LUMO interactions between the carbene and alkene. Similarly, a correlation was found for the global electrophilicity parameter, ω , and the ΔN_{max} parameters (see Topic 1.5, Part A for definition of these DFT-based parameters).¹²³

10.2.2. Generation of Carbenes

There are several ways of generating carbene intermediates. Some of the most general routes are summarized in Scheme 10.8 and are discussed in the succeeding paragraphs.

10.2.2.1. Carbenes from Diazo Compounds. Decomposition of diazo compounds to form carbenes is a quite general reaction that is applicable to diazomethane and other diazoalkanes, diazoalkenes, and diazo compounds with aryl and acyl substituents. The main restrictions on this method are the limitations on synthesis and limited stability of the diazo compounds. The smaller diazoalkanes are toxic and potentially explosive, and they are usually prepared immediately before use. The most general synthetic routes involve base-catalyzed decomposition of *N*-nitroso derivatives of amides, ureas, or sulfonamides, as illustrated by several reactions used for the preparation of diazomethane.

The details of the base-catalyzed decompositions vary somewhat but the mechanisms involve two essential steps.¹²⁸ The initial reactants undergo a base-catalyzed addition-elimination to form an alkyl diazoate. This is followed by a deprotonation of the α -carbon and elimination of hydroxide.

Diazo compounds can also be obtained by oxidation of the corresponding hydrazone,¹²⁹ the route that is most common when one of the substituents is an aromatic ring.

The higher diazoalkanes can be made by $\text{Pb}(\text{O}_2\text{CCH}_3)_2$ oxidation of hydrazones.¹²⁹

α -Diazoketones are especially useful in synthesis.¹³¹ There are several methods of preparation. Reaction of diazomethane with an acyl chloride results in formation of a diazomethyl ketone.

The HCl generated in this reaction destroys one equivalent of diazomethane, but this can be avoided by including a base, such as triethylamine, to neutralize the acid.¹³²

Cyclic α -diazoketones, which are not available from acyl chlorides, can be prepared by reaction of an enolate equivalent with a sulfonyl azide, in a reaction known as *diazo transfer*.¹³³ Various arenesulfonyl azides¹³⁴ and methanesulfonyl azide¹³⁵ are used most frequently. Because of the potential explosion hazard of sulfonyl azides, safety is a factor in choosing the reagent. 4-Dodecylbenzenesulfonyl azide has been recommended on the basis of relative thermal stability.¹³⁶ This reagent has been used in an *Organic Synthesis* preparation of 1-diazo-4-phenylprop-2-enone.¹³⁷

A polymer bound arenesulfonyl azide can be prepared from polystyrene.¹³⁸

This reagent effects diazo transfer in good yield.

Several types of compounds can act as the carbon nucleophile in diazo transfer, including the oxymethylene¹³⁹ or dialkylaminomethylene¹⁴⁰ derivatives of the ketone. These activating substituents are lost during these reactions.

α -Trifluoroacetyl derivatives of ketones are also useful substrates for diazo transfer reactions.¹⁴¹ They are made by enolate acylation using 2,2,2-trifluoroethyl trifluoroacetate. The trifluoroacetyl group is cleaved during diazo transfer.

Benzoyl groups are also selectively cleaved during diazo transfer. This method has been used to prepare diazo ketones and diazo esters.¹⁴²

α -Diazo ketones can also be made by first converting the ketone to an α -oximino derivative by nitrosation and then oxidizing the oximino ketone with chloramine.¹⁴³

Ref. 144

α -Diazo esters can be prepared by esterification of alcohols with the tosylhydrazide of glyoxyloyl chloride, followed by reaction with triethylamine.¹⁴⁵

The driving force for decomposition of diazo compounds to carbenes is the formation of the very stable nitrogen molecule. Activation energies for decomposition of diazoalkanes in the gas phase are about 30 kcal/mol. The requisite energy can also be supplied by photochemical excitation. It is often possible to control the photochemical process to give predominantly singlet or triplet carbene. Direct photolysis leads to the singlet intermediate when the dissociation of the excited diazoalkene is faster than intersystem crossing to the triplet state. The triplet carbene is the principal intermediate in photosensitized decomposition of diazoalkanes. (See Part A, Chapter 12 to review photosensitization.)

Reaction of diazo compounds with a variety of transition metal compounds leads to evolution of nitrogen and formation of products of the same general type as those formed by thermal and photochemical decomposition of diazoalkanes. These transition

metal-catalyzed reactions involve carbenoid intermediates in which the carbene is bound to the metal.¹⁴⁶ The metals that have been used most frequently in synthetic reactions are copper and rhodium, and these reactions are discussed in Section 10.2.3.2

10.2.2.2. Carbenes from Sulfonylhydrazones. The second method listed in Scheme 10.8, thermal or photochemical decomposition of salts of arenesulfonylhydrazones, is actually a variation of the diazoalkane method, since diazo compounds are intermediates. The conditions of the decomposition are usually such that the diazo compound reacts immediately on formation.¹⁴⁷ The nature of the solvent plays an important role in the outcome of sulfonylhydrazone decompositions. In protic solvents, the diazoalkane can be diverted to a carbocation by protonation.¹⁴⁸ Aprotic solvents favor decomposition via the carbene pathway.

10.2.2.3. Carbenes from Diazirines. The diazirine precursors of carbenes (Scheme 10.8, Entry 3) are cyclic isomers of diazo compounds. The strain of the small ring and the potential for formation of nitrogen make them highly reactive toward loss of nitrogen on photoexcitation. Diazirines have been used mainly in mechanistic investigations of carbenes. They are, in general, somewhat less easily available than diazo compounds or arenesulfonylhydrazones. However, there are several useful synthetic routes.¹⁴⁹

10.2.2.4. Carbenes from Halides by α -Elimination. The α -elimination of hydrogen halide induced by strong base (Scheme 10.8, Entry 4) is restricted to reactants that do not have β -hydrogens, because dehydrohalogenation by β -elimination dominates when it can occur. The classic example of this method of carbene generation is the generation of dichlorocarbene by base-catalyzed decomposition of chloroform.¹⁵²

Both phase transfer and crown ether catalysis have been used to promote α -elimination reactions of chloroform and other haloalkanes.¹⁵³ The carbene can be trapped by alkenes to form dichlorocyclopropanes.

Ref. 154

Dichlorocarbene can also be generated by sonication of a solution of chloroform with powdered KOH.¹⁵⁵

α -Elimination also occurs in the reaction of dichloromethane and benzyl chlorides with alkylolithium reagents. The carbanion stabilization provided by the chloro and phenyl groups makes the lithiation feasible.

Ref. 156

Ref. 157

The reactive intermediates under some conditions may be the carbenoid α -haloalkyllithium compounds or carbene-lithium halide complexes.¹⁵⁸ In the case of the trichloromethylithium to dichlorocarbene conversion, the equilibrium lies heavily to the side of trichloromethylithium at -100°C .¹⁵⁹ The addition reaction with alkenes seems to involve dichlorocarbene, however, since the pattern of reactivity toward different alkenes is identical to that observed for the free carbene in the gas phase.¹⁶⁰

A method that provides an alternative route to dichlorocarbene is the decarboxylation of trichloroacetic acid.¹⁶¹ The decarboxylation generates the trichloromethyl anion, which decomposes to the carbene. Treatment of alkyl trichloroacetates with an alkoxide also generates dichlorocarbene.

The applicability of these methods is restricted to polyhalogenated compounds, since the inductive effect of the halogen atoms is necessary for facilitating formation of the carbanion.

Hindered lithium dialkylamides can generate aryl-substituted carbenes from benzyl halides.¹⁶² Reaction of α,α -dichlorotoluene or α,α -dibromotoluene with potassium *t*-butoxide in the presence of 18-crown-6 generates the corresponding α -halophenylcarbene.¹⁶³ The relative reactivity data for carbenes generated under these latter conditions suggest that they are “free.” The potassium cation would be expected to be strongly solvated by the crown ether and it is evidently not involved in the carbene-generating step.

10.2.2.5. Carbenes from Organomercury Compounds. The α -elimination mechanism is also the basis for the use of organomercury compounds for carbene generation (Scheme 10.8, Entry 5). The carbon-mercury bond is much more covalent than the C–Li bond, however, so the mercury reagents are generally stable at room temperature and can be isolated. They decompose to the carbene on heating.¹⁶⁴ Addition reactions occur in the presence of alkenes. The decomposition rate is not greatly influenced by the alkene. This observation implies that the rate-determining step is generation of the carbene from the organomercury precursor.¹⁶⁵

A variety of organomercury compounds that can serve as precursors of substituted carbenes have been synthesized. For example, carbenes with carbomethoxy or trifluoromethyl substituents can be generated in this way.¹⁶⁶

The addition reaction of alkenes and phenylmercuric bromide typically occurs at about 80°C. Phenylmercuric iodides are somewhat more reactive and may be advantageous in reactions with relatively unstable alkenes.¹⁶⁷

10.2.3. Addition Reactions

Addition reactions with alkenes to form cyclopropanes are the most studied reactions of carbenes, both from the point of view of understanding mechanisms and for synthetic applications. A concerted mechanism is possible for singlet carbenes. As a result, the stereochemistry present in the alkene is retained in the cyclopropane. With triplet carbenes, an intermediate 1,3-diradical is involved. Closure to cyclopropane requires spin inversion. The rate of spin inversion is slow relative to rotation about single bonds, so mixtures of the two possible stereoisomers are obtained from either alkene stereoisomer.

Reactions involving free carbenes are very exothermic since two new σ bonds are formed and only the alkene π bond is broken. The reactions are very fast and, in fact, theoretical treatment of the addition of singlet methylene to ethylene suggests that there is no activation barrier.¹⁶⁸ The addition of carbenes to alkenes is an important method for synthesis of many types of cyclopropanes and several of the methods for carbene generation listed in Scheme 10.8 have been adapted for use in synthesis. Scheme 10.9, at the end of this section, gives a number of specific examples.

10.2.3.1. Cyclopropanation with Halomethylzinc Reagents. A very effective means for conversion of alkenes to cyclopropanes by transfer of a CH_2 unit involves reaction with methylene iodide and a zinc-copper couple, referred to as the *Simmons-Smith reagent*.¹⁶⁹ The reactive species is iodomethylzinc iodide.¹⁷⁰ The transfer of methylene occurs stereospecifically. Free $:CH_2$ is not an intermediate. Entries 1 to 3 in Scheme 10.9 are typical examples.

A modified version of the Simmons-Smith reaction uses dibromomethane and in situ generation of the Cu-Zn couple.¹⁷¹ Sonication is used in this procedure to promote reaction at the metal surface.

Ref. 172

Another useful reagent combination involves diethylzinc and diiodomethane or chloriodomethane.

Ref. 173

Several modifications of the Simmons-Smith procedure have been developed in which an electrophile or Lewis acid is included. Inclusion of acetyl chloride accelerates the reaction and permits the use of dibromomethane.¹⁷⁴ Titanium tetrachloride has similar effects in the reactions of unfunctionalized alkenes.¹⁷⁵ Reactivity can be enhanced by inclusion of a small amount of trimethylsilyl chloride.¹⁷⁶ The Simmons-Smith reaction has also been found to be sensitive to the purity of the zinc used. Electrolytically prepared zinc is much more reactive than zinc prepared by metallurgic smelting, and this has been traced to small amounts of lead in the latter material.

The nature of reagents prepared under different conditions has been explored both structurally and spectroscopically.¹⁷⁷ $\text{C}_2\text{H}_5\text{ZnCH}_2\text{I}$, $\text{Zn}(\text{CH}_2\text{I})_2$, and ICH_2ZnI are all active methylene transfer reagents.

A crystal structure has been obtained for $\text{Zn}(\text{CH}_2\text{I})_2$ complexed with *exo,exo*-2,3-dimethoxybornane and is shown in Figure 10.4.

Computational studies were done on several ClZnCH_2Cl models, and the results are summarized in Figure 10.5.¹⁷⁸ A minimal TS consisting of ClZnCH_2Cl and ethene shows charge transfer mainly to the departing Cl; that is, the ethene displaces chloride in the zinc coordination sphere. The model can be elaborated by inclusion of ZnCl_2 ,

which is present under most experimental conditions and can have an accelerating effect. Models were also calculated for the directing and activating effect of allylic hydroxy groups. Definitive results were not obtained for this case, but an aggregated structure with the oxygen coordinated to zinc is plausible.

Other reagents have been developed in which one of the zinc ligands is an oxy anion. Compounds with trifluoroacetate anions are prepared by protonolysis of C_2H_5 or CH_2I groups on zinc.¹⁷⁹

Iodomethylzinc phenoxides can be prepared in a similar fashion. The best phenols are the 2,4,6-trihalophenols and the readily available 2,4,6-trichlorophenol was examined most thoroughly.¹⁸⁰

This reagent can achieve better than 90% yields for a variety of unactivated alkenes.

The reactivity of the oxy anions is in the order $\text{CF}_3\text{CO}_2^- > \text{ArO}^- \gg \text{RO}^-$.

In molecules containing hydroxy groups, the CH₂ unit is selectively introduced on the side of the double bond *syn* to the hydroxy group in the Simmons-Smith reaction and related cyclopropanations. This indicates that the reagent is complexed to the hydroxy group and that the complexation facilitates the addition. Entries 3 and 4 in Scheme 10.9 illustrate the stereodirective effect of the hydroxy group. It is evidently the Lewis base character of the group that is important, in contrast to the hydrogen bonding that is involved in epoxidation. The lithium salts of allylic alcohols are also strongly activated, even more so than the alcohols. This reactivity has been used to advantage in the preparation of relatively unstable products.¹⁸¹

While amino groups alone are not effective directing groups, both ephedrine and pseudoephedrine derivatives give high diastereoselectivity. This is evidently due to chelation by the hydroxy group, as both auxiliaries give the same facial selectivity despite differing in configuration at the nitrogen position.¹⁸²

Dioxolanyl oxygens are also effective directing groups.¹⁸³

Ref. 185

The stereoselectivity is accounted for by a TS in which the allylic oxygen is coordinated to the zinc.

The directive effect of allylic hydroxy groups can be used in conjunction with chiral catalysts to achieve enantioselective cyclopropanation. The chiral ligand used is a boronate ester derived from the *N,N,N',N'*-tetramethyl amide of tartaric acid.¹⁸⁶ Similar results are obtained using the potassium alkoxide, again indicating the Lewis base character of the directive effect.

These conditions were used to make natural products containing several successive cyclopropane rings.¹⁸⁷

10.2.3.2. Metal-Catalyzed Cyclopropanation. Carbene addition reactions can be catalyzed by several transition metal complexes. Most of the synthetic work has been done using copper or rhodium complexes and we focus on these. The copper-catalyzed decomposition of diazo compounds is a useful reaction for formation of substituted cyclopropanes.¹⁸⁸ The reaction has been carried out with several copper salts,¹⁸⁹ and both Cu(I) and Cu(II) triflate are useful.¹⁹⁰ Several Cu(II)salen complexes, such as the *N*-*t*-butyl derivative, which is called Cu(TBS)₂, have become popular catalysts.¹⁹¹

Ref. 192

An NMR and structural study characterized the intermediates generated from diimine catalysts on reaction with diazodiphenylmethane.¹⁹³ The dominant species in solution is dinuclear, but a monomeric metalcarbene species can be detected.

The monomeric species can be isolated as a solid in the case of the *N,N'*-dimesityl derivative. The crystal structures of both dimeric and monomeric structures are shown in Figure 10.6.

There has also been computational investigation of copper-catalyzed carbenoid addition reactions, as shown in Figure 10.7.¹⁹⁴ These computational studies agree with experimental investigations in identifying nitrogen extrusion as the rate-determining step. The addition step is a direct carbene transfer, as opposed to involving a metallo-cyclobutane intermediate.

Various other transition metal complexes are also useful, including rhodium,¹⁹⁵ palladium,¹⁹⁶ and molybdenum¹⁹⁷ compounds. The catalytic cycle can generally be represented as shown below.¹⁹⁸

The metal-carbene complexes are electrophilic in character. They can, in fact, be represented as metal-stabilized carbocations.

In most transition metal-catalyzed reactions, one of the carbene substituents is a carbonyl group, which further enhances the electrophilicity of the intermediate. There are two general mechanisms that can be considered for cyclopropane formation. One involves formation of a four-membered ring intermediate that incorporates the metal. The alternative represents an electrophilic attack giving a polar species that undergoes 1,3-bond formation.

Since the additions are normally stereospecific with respect to the alkene, if an open-chain intermediate is involved it must collapse to product more rapidly than single-bond rotations that would destroy the stereoselectivity.

In recent years, much attention has been focused on rhodium-mediated carbenoid reactions. One goal has been to understand how the rhodium ligands control reactivity and selectivity, especially in cases in which both addition and insertion reactions are possible. These catalysts contain Rh–Rh bonds but function by mechanisms similar to other transition metal catalysts.

The original catalyst was $\text{Rh}_2(\text{O}_2\text{CCH}_3)_4$, but other carboxylates such as nonafluorobutanoate and amide anions, such as those from acetamide and caprolactam, also have good catalytic activity.¹⁹⁹

The ligands adjust the electrophilicity of the catalyst with the nonafluorobutanoate being more electrophilic and the amido ligands less electrophilic than the acetate. These catalysts show differing reactivity. For example, $\text{Rh}_2(\text{O}_2\text{C}_4\text{F}_9)_4$ was found to favor aromatic substitution over cyclopropanation, whereas $\text{Rh}_2(\text{caprolactamate})_4$ was selective for cyclopropanation.²⁰⁰ In competition between tertiary alkyl insertion versus cyclopropanation, the order in favor of cyclopropanation is also $\text{Rh}_2(\text{caprolactamate})_4 > \text{Rh}_2(\text{O}_2\text{CCH}_3)_4 > \text{Rh}_2(\text{O}_2\text{CC}_4\text{F}_9)_4$. These predictable selectivity patterns have made the rhodium catalysts useful in a number of synthetic applications.²⁰¹ For example, $\text{Rh}_2(\text{O}_2\text{C}_4\text{F}_9)_4$ gave exclusively insertion, whereas $\text{Rh}_2(\text{caprolactamate})_4$ gave exclusively cyclopropanation. $\text{Rh}_2(\text{O}_2\text{CCH}_3)_4$ gave a mixture of the two products.²⁰²

Mechanistic and computational studies have elucidated some of the key details of the reactions. A kinetic study of $\text{Rh}_2[\text{O}_2\text{CC}(\text{CH}_3)_3]_4$ involving several different reaction types established that the rate-determining step in the rhodium-catalyzed reactions is loss of nitrogen.²⁰³ The basic mechanism and reaction energy profile are given in Figure 10.8. In addition, certain reactants and solvents were shown to have an inhibitory effect by competing with the diazo compound for coordination at the rhodium center. For example, anisole has such an effect.

Another study combined measurement of kinetic isotope effects with computational modeling of the TS.²⁰⁴ The computed energy profile suggests that there is no barrier for the reaction of styrene with the carbene complex from methyl diazoacetate. In contrast, a barrier of about 12 kcal/mol is found for methyl 2-diazobut-3-enoate. This is consistent with experimental work showing that alkenyl and aryl-substituted diazo esters have greater selectivity. Figure 10.9 shows the computed TS for the reaction of the phenyl-substituted ester with styrene. The addition is highly asynchronous and has an early TS. The kinetic isotope effects calculated for this model are in excellent agreement with the experimental values.

This study also gives a good account of the stereoselectivity of the 2-diazobut-3-enoate addition reaction with styrene. There is a preference for the ester group

to be *trans* to the phenyl group. The calculated difference between the two TSs is 1.7 kcal/mol. The main difference is the closer approach of the phenyl group to the ester oxygen in the disfavored TS. Steric interactions with the ester group also explain why *trans*-disubstituted alkenes are unreactive with this catalyst, whereas *cis*-alkenes are reactive (see Figure 10.10). We will see shortly that the same TS feature can account for the enantioselectivity of chiral rhodium catalysts.

As would be expected for a highly electrophilic species, rhodium-catalyzed carbenoid additions are accelerated by aryl substituents, as well as by other cation-stabilizing groups on the alkene reactant.²⁰⁵ When applied to 1,1-diarylethenes, ERG substituents favor the position *trans* to the ester group.²⁰⁶ This can be understood in terms of maximizing the interaction between this ring and the reacting double bond.

10.2.3.3. Other Cyclopropanation Methods. Haloalkylmercury compounds are also useful in synthesis. The addition reactions are usually carried out by heating the organomercury compound with the alkene. Two typical examples are given in Section C of Scheme 10.9.

The addition of dichlorocarbene, generated from chloroform, to alkenes gives dichlorocyclopropanes. The procedures based on lithiated halogen compounds have been less generally used in synthesis. Section D of Scheme 10.9 gives a few examples of addition reactions of carbenes generated by α -elimination.

10.2.3.4. Examples of Cyclopropanations. Scheme 10.9 illustrates some of these cyclopropanation methods. Section A pertains to the Simmons-Smith type of cyclopropanation. Entry 1 is an example using readily available sources of the cyclopropanation reagent. Only a modest excess of the reagents was needed, and good yields were obtained from several unfunctionalized cycloalkenes under these conditions. Entry 2 is a case of an allylic alcohol and illustrates the hydroxy-directing effect. Entries 3 to 6 are also examples of the directive effect of hydroxy groups in ring systems. Entry 4 was done using the diethylzinc-diiodomethane conditions. The vinyl ether group is expected to be quite reactive because of the electrophilic character of the methylene transfer reaction. Entry 5 illustrates the application of the hydroxy-directing

effect in an acyclic system. Not only is the hydroxy group stereodirective, but it also provides selectivity with respect to the two double bonds. The reaction in Entry 6 was carried out in the course of synthesis of crenulide derivatives, which are obtained from seaweed.

Section B gives some examples of metal-catalyzed cyclopropanations. In Entries 7 and 8, Cu(I) salts are used as catalysts for intermolecular cyclopropanation by ethyl diazoacetate. The *exo* approach to norbornene is anticipated on steric grounds. In both cases, the Cu(I) salts were used at a rather high ratio to the reactants. Entry 9 illustrates use of $\text{Rh}_2(\text{O}_2\text{CCH}_3)_4$ as the catalyst at a much lower ratio. Entry 10 involves ethyl diazopyruvate, with copper acetylacetonate as the catalyst. The stereoselectivity of this reaction was not determined. Entry 11 shows that $\text{Pd}(\text{O}_2\text{CCH}_3)_2$ is also an active catalyst for cyclopropanation by diazomethane.

Section C shows cases involving organomercury reagents, which are useful for introducing functionalized cyclopropane rings when the necessary reagents can be obtained as mercury compounds. The very vigorous conditions needed for these reactions indicate the relatively low reactivity of the organomercury compounds toward α -elimination.

Section D illustrates formation of carbenes from halides by α -elimination. The carbene precursors are formed either by deprotonation (Entries 14 and 17) or halogen-metal exchange (Entries 15 and 16). The carbene additions can take place at low temperature. Entry 17 is an example of generation of dichlorocarbene from chloroform under phase transfer conditions.

Intramolecular carbene addition reactions have a special importance in the synthesis of strained-ring compounds. Because of the high reactivity of carbene or carbenoid species, the formation of highly strained bonds is possible. The strategy for synthesis is to construct a potential carbene precursor, such as a diazo compound or di- or trihalo compound that can undergo intramolecular addition to give the desired structure. Section E of Scheme 10.9 gives some representative examples. Entries 18 and 19 are cases of formation of strained compounds. The reaction in Entry 20 shows a preference between the two double bonds, based on proximity, and establishes a ring system that subsequently undergoes a divinylcyclopropane rearrangement to generate a nine-membered ring.

10.2.3.5. Enantioselective Cyclopropanation. Enantioselective versions of both copper and rhodium cyclopropanation catalysts are available. The copper-imine class of catalysts is enantioselective when chiral imines are used. Some of the chiral ligands that have been utilized in conjunction with copper salts are shown in Scheme 10.10.

Several chiral ligands have been developed for use with the rhodium catalysts, among them are pyrrolidinones and imidazolidinones.²⁰⁷ For example, the lactamate of pyroglutamic acid gives enantioselective cyclopropanation reactions.

Zhou, and S. F. Martin, *J. Am. Chem. Soc.*, **117**, 5763 (1995); M. P. Doyle, A. B. Dyatkin, M. N. Protopopova, C. I. Yang, G. S. Miertschin, W. R. Winchester, S. H. Simonsen, V. Lynch, and R. Ghosh, *Rec. Trav. Chim. Pays-Bas*, **114**, 163 (1995); M. P. Doyle, *Pure Appl. Chem.*, **70**, 1123 (1998); M. P. Doyle and M. N. Protopopova, *Tetrahedron*, **54**, 7919 (1998); M. P. Doyle and D. C. Forbes, *Chem. Rev.*, **98**, 911 (1998).

The 1-acetyl and 1-benzoyl derivatives of 4-carbomethoxyimidazolinone are also effective catalysts. Another group of catalysts is made up of *N*-arenesulfonylprolinates. The structures and abbreviations are given in Scheme 10.11. The PY series of catalysts is derived from pyroglutamic acid, whereas the IM and OX designations apply to imidazolines and oxazolines, respectively. The designations ME and NE refer to methyl and neopentyl *esters*, and MA and PA indicate *amides* of acetic acid and phenylacetic acid, respectively. Only two of the four ligands that are present are shown.

A comparison of several of the PY and IM types of catalysts in intramolecular reactions of allylic diazoacetates led to a consistent model for the enantioselectivity. The highest e.e. values are observed for *cis*-substituted allylic esters. Both R^t and R^i are directed toward the catalyst and introduce steric interactions that detract from enantioselectivity.²⁰⁸

The 1-arenesulfonylprolinate catalysts have been studied computationally.²⁰⁹ A computed TS and conceptual model that is consistent with experimentally observed enantioselectivity is shown in Figure 10.11. The arenesulfonyl groups block one of the directions of approach to the carbene catalyst and also orient the alkene substituent away from the metal center.

Several of the copper and rhodium catalysts were compared in an intramolecular cyclopropanation.²¹⁰ For the reaction leading to formation of a 10-membered ring, shown below, the copper catalysts gave higher enantioselectivity, but there were many subtleties, depending on ring size and other structural features in related systems.

Scheme 10.12 gives some examples of enantioselective cyclopropanations. Entry 1 uses the *bis-t*-butyloxazoline (BOX) catalyst. The catalytic cyclopropanation in Entry 2 achieves both stereo- and enantioselectivity. The electronic effect of the catalysts (see p. 926) directs the alkoxy-substituted ring *trans* to the ester substituent (87:13 ratio), and very high enantioselectivity was observed. Entry 3 also used the *t*-butyl-BOX catalyst. The product was used in an enantioselective synthesis of the alkaloid quebrachamine. Entry 4 is an example of enantioselective methylene transfer using the tartrate-derived dioxaborolane catalyst (see p. 920). Entry 5 used the $\text{Rh}_2[5(S)\text{-MePY}]_4$

catalyst. Entry 6 is an intramolecular cyclopropanation done using a *bis*-(oxazolynyl) biphenyl catalyst (see Scheme 10.10, Entry 5).

10.2.4. Insertion Reactions

Insertion reactions are processes in which a reactive intermediate, in this case a carbene, interposes itself into an existing bond. In terms of synthesis, this usually involves C–H bonds. Many singlet carbenes are sufficiently reactive that insertion can occur as a one-step process.

The same products can be formed by a two-step hydrogen abstraction and recombination involving a triplet carbene.

It is sometimes difficult to distinguish clearly between these mechanisms, but determination of reaction stereochemistry provides one approach. The true one-step insertion must occur with complete *retention of configuration*. The results for the two-step process will depend on the rate of recombination in competition with stereorandomization of the radical pair intermediate.

Owing to the high reactivity of the intermediates involved, intermolecular carbene insertion reactions are not very selective. The distribution of products from the photolysis of diazomethane in heptane, for example, is almost exactly that expected on a statistical basis.²¹¹

Corey, *Tetrahedron Lett.*, **36**, 8745 (1995).

Rhodium carboxylates have been found to be effective catalysts for intramolecular C–H insertion reactions of α -diazo ketones and esters.²¹⁵ In flexible systems, five-membered rings are formed in preference to six-membered ones. Insertion into methine hydrogen is preferred to a methylene hydrogen. Intramolecular insertion can be competitive with intramolecular addition. Product ratios can to some extent be controlled by the specific rhodium catalyst that is used.²¹⁶ In the example shown, insertion is the exclusive reaction with $\text{Rh}_2(\text{O}_2\text{CC}_4\text{F}_9)_4$, whereas only addition occurs with $\text{Rh}_2(\text{caprolactamate})_4$, which indicates that the more electrophilic carbenoids favor insertion.

²¹⁶ (a) M. P. Doyle, L. J. Westrum, W. N. E. Wolthuis, M. M. See, W. P. Boone, V. Bagheri, and M. M. Pearson, *J. Am. Chem. Soc.*, **115**, 958 (1993); (b) A. Padwa and D. J. Austin, *Angew. Chem. Int. Ed. Engl.*, **33**, 1797 (1994).

When the reactant provides more than one kind of hydrogen for insertion, the catalyst can influence selectivity. For example, $\text{Rh}_2(\text{acam})_4$ gives exclusively insertion at a tertiary position, whereas $\text{Rh}_2(\text{O}_2\text{CC}_4\text{F}_9)_4$ leads to nearly a statistical mixture.^{217a} The attenuated reactivity of the amidate catalyst enhances selectivity.

Stereoselectivity is also influenced by the catalysts. For example, **16** can lead to either *cis* or *trans* products. Although $\text{Rh}_2(\text{O}_2\text{CCH}_3)_4$ is unselective, the $\text{Rh}_2(\text{MACIM})_4$ catalyst **11-5** (Scheme 10.11) is selective for the *cis* isomer and also gives excellent enantioselectivity in the major product.²¹⁷

Certain sterically hindered rhodium catalysts also lead to improved selectivity. For example, rhodium triphenylacetate improves the selectivity for **17** over **18** from 5:1 to 99:1.²¹⁸

Allylic ethers and acetals can react with carbenoid reagents to generate oxonium ylides that undergo [2,3]-sigmatropic shifts.²²⁴

10.2.6. Rearrangement Reactions

The most common rearrangement reaction of alkyl carbenes is the shift of hydrogen, generating an alkene. This mode of stabilization predominates to the exclusion of most intermolecular reactions of aliphatic carbenes and often competes with intramolecular insertion reactions. For example, the carbene generated by decomposition of the tosylhydrazone of 2-methylcyclohexanone gives mainly 1- and 3-methylcyclohexene rather than the intramolecular insertion product.

Carbenes can also be stabilized by migration of alkyl or aryl groups. 2-Methyl-2-phenyl-1-diazopropane provides a case in which products of both phenyl and methyl migration, as well as intramolecular insertion, are observed.

If this reaction proceeds in a concerted fashion, a carbene intermediate is avoided. Mechanistic studies have been aimed at determining whether migration is concerted with the loss of nitrogen. The conclusion that has emerged is that a carbene is generated in photochemical reactions but that the reaction can be concerted under thermal conditions.

A related issue is whether the carbene, when it is involved, is in equilibrium with a ring-closed isomer, an oxirene.²³³ This aspect of the reaction has been probed using isotopic labeling. If a symmetrical oxirene is formed, the label should be distributed to both the carbonyl and α -carbon. A concerted reaction or a carbene intermediate that did not equilibrate with the oxirene should have label only in the carbonyl carbon. The extent to which the oxirene is formed depends on the structure of the diazo compound. For diazoacetaldehyde, photolysis leads to only 8% migration of label, which would correspond to formation of 16% of the product through the oxirene.²³⁴

The diphenyl analog shows about 20–30% rearrangement.²³⁵ α -Diazocyclohexanone gives no evidence of an oxirene intermediate, since all the label remains at the carbonyl carbon.²³⁶

The reactivity of diazo carbonyl compounds appears to be related to the conformational equilibria between *s-cis* and *s-trans* conformations. A concerted rearrangement is favored by the *s-cis* conformation.²³⁷ The *t*-butyl compound **19**, which exists in the *s-trans* conformation, gives very little di-*t*-butylketene on photolysis.²³⁸ A similarly

substituted cyclic diazoketone **20**, which is in the *s-cis* conformation, gives a high yield of the ring-contracted ketene.²³⁹

In a flash photolysis study of a series of diazo carbonyl compounds, a correlation was found between the amount of carbene that could be trapped by pyridine and the amount of *s-trans* ketone.²⁴⁰

Flash photolysis of benzoyl and naphthoyl diazomethane, which should exist in the *s-cis* conformation, led to ketene intermediates within the duration of the pulse (~ 20 ns).²⁴¹

The main synthetic application of the Wolff rearrangement is for the one-carbon homologation of carboxylic acids.²⁴² In this procedure, a diazomethyl ketone is synthesized from an acyl chloride. The rearrangement is then carried out in a nucleophilic solvent that traps the ketene to form a carboxylic acid (in water) or an ester (in alcohols). Silver oxide is often used as a catalyst, since it seems to promote the rearrangement over carbene formation.²⁴³

The photolysis of cyclic α -diazoketones results in ring contraction to a ketene, which can be isolated as the corresponding ester.

Scheme 10.14 gives some other examples of Wolff rearrangement reactions. Entries 1 and 2 are reactions carried out under the classical silver ion catalysis conditions. Entry 3 is an example of a thermolysis. Entries 4 to 7 are ring contractions done under photolytic conditions. Entry 8, done using a silver catalyst, was a step in the synthesis of mabcetin, an antitumor antibiotic. Entry 9, a step in the synthesis of a drug candidate, illustrates direct formation of an amide by trapping the ketene intermediate with an amine.

10.2.8. Nitrenes and Related Intermediates

The nitrogen analogs of carbenes are called nitrenes. As with carbenes, both singlet and triplet electronic states are possible.

The triplet state is usually the ground state for non-conjugated structures, but either species can be involved in reactions. The most common method for generating nitrene intermediates, analogous to formation of carbenes from diazo compounds, is by thermolysis or photolysis of azides.²⁴⁶

The types of azides that have been used for generation of nitrenes include alkyl,²⁴⁷ aryl,²⁴⁸ acyl,²⁴⁹ and sulfonyl²⁵⁰ derivatives.

The characteristic reaction of an alkyl nitrene is migration of one of the substituents to nitrogen, giving an imine.

Intramolecular insertion and addition reactions are very rare for alkyl nitrenes. In fact, it is not clear that the nitrenes are formed as discrete species. The migration may be concerted with elimination, as is often the case in the Wolff rearrangement.²⁵¹

Aryl nitrenes also generally rearrange rather than undergo addition or insertion reactions.²⁵²

A few intramolecular insertion reactions, especially in aromatic systems, go in good yield.²⁵³

The nitrenes that most consistently give addition and insertion reactions are carboalkoxynitrenes generated from alkyl azidoformates.

These intermediates undergo addition reactions with alkenes and aromatic compounds and insertion reactions with saturated hydrocarbons.²⁵⁴

Carboalkoxynitrenes are somewhat more selective than the corresponding carbenes, showing selectivities of roughly 1:10:40 for the primary, secondary, and tertiary positions in 2-methylbutane in insertion reactions.

Sulfonylnitrenes are formed by thermal decomposition of sulfonyl azides. Insertion reactions occur with saturated hydrocarbons.²⁵⁵ With aromatic compounds the main products are formally insertion products, but they are believed to be formed through addition intermediates.

Ref. 257

Aziridination of alkenes can be carried out using *N*-(*p*-toluenesulfonylimino) phenyliodine and copper triflate or other copper salts.²⁵⁷ These reactions are mechanistically analogous to metal-catalyzed cyclopropanation. Rhodium acetate also acts as a catalyst.²⁵⁸ Other arenesulfonyliminoiodinanes can be used,²⁵⁹ as can chloroamine T²⁶⁰ and bromoamine T.²⁶¹ The range of substituted alkenes that react includes acrylate esters.²⁶²

10.2.9. Rearrangements to Electron-Deficient Nitrogen

In contrast to the rather limited synthetic utility of nitrenes, there is an important group of reactions in which migration occurs to electron-deficient nitrogen. One of the most useful of these reactions is the *Curtius rearrangement*,²⁶³ which has the same relationship to acyl nitrene intermediates that the Wolff rearrangement has to acyl carbenes. This reaction is usually considered to be a concerted process in which migration accompanies loss of nitrogen.²⁶⁴ The temperature required for reaction is in the vicinity of 100°C. The initial product is an isocyanate that can be isolated or trapped by a nucleophilic solvent. The migrating group retains its stereochemical configuration.

The acyl azide intermediates are prepared either by reaction of sodium azide with a reactive acylating agent or by diazotization of an acyl hydrazide. An especially convenient version of the former process is treatment of the carboxylic acid with ethyl chloroformate to form a mixed anhydride, which then reacts with azide ion.²⁶⁵

The transformation can also be carried out on the acid using diphenylphosphoryl azide (DPPA).²⁶⁶

This version of the Curtius rearrangement has been applied to the synthesis of amino acid analogs and structures containing amino acids. Several *cis*-2-aminocyclopropane carboxylate esters were prepared by selective hydrolysis of cyclopropane-1,2-dicarboxylates, followed by reaction with DPPA.²⁶⁷

The Curtius reaction has occasionally been used in formation of medium²⁶⁸ and large²⁶⁹ rings, usually in modest yield.

Another reaction that can be used for conversion of carboxylic acids to the corresponding amines with loss of carbon dioxide is the *Hofmann rearrangement*. The classic reagent is hypobromite ion, which reacts to form an *N*-bromoamide intermediate. Like the Curtius reaction, this rearrangement is believed to be a concerted process and proceeds through an isocyanate intermediate.

The reaction is useful in the conversion of aromatic carboxylic acids to aromatic amines.

Ref. 270

Use of *N*-bromosuccinimide in the presence of sodium methoxide or DBU in methanol traps the isocyanate intermediate as a carbamate.²⁷¹

Direct oxidation of amides can also lead to Hofmann-type rearrangement with formation of amines or carbamates. One reagent that is used is Pb(O₂CCH₃)₄.

Ref. 280

These reactions are especially favorable for β - and γ -hydroxy azides, where reaction can proceed through a hemiketal intermediate.

Ref. 281

Another important reaction involving migration to electron-deficient nitrogen is the *Beckmann rearrangement*, in which oximes are converted to amides.²⁸²

A variety of protic acids, Lewis acids, acid anhydrides, or acyl and sulfonyl halides can cause the reaction to occur. The mechanism involves conversion of the oxime hydroxy group to a leaving group. Ionization and migration then occur as a concerted process, with the group that is *anti* to the oxime leaving group migrating. The migration results in formation of a nitrilium ion, which captures a nucleophile. Eventually hydrolysis leads to the amide.

React.*, **35**, 1 (1988).

The migrating group retains its configuration. Some reaction conditions can lead to *syn-anti* isomerization at a rate exceeding rearrangement, and when this occurs, a mixture of products is formed. The reagents that have been found least likely to cause competing isomerization are phosphorus pentachloride and *p*-toluenesulfonyl chloride.²⁸³

A fragmentation reaction occurs if one of the oxime substituents can give rise to a relatively stable carbocation. Fragmentation is very likely to occur if a nitrogen, oxygen, or sulfur atom is present α to the oximino group.

Fragmentation can also occur when the α -carbon can support cationic character.

Ref. 284

Section D of Scheme 10.15 provides some examples of the Beckmann rearrangement.

Section A of Scheme 10.15 contains a number of examples of Curtius rearrangements. Entry 1 is an example carried out in a nonnucleophilic solvent, permitting isolation of the isocyanate. Entries 2 and 3 involve isolation of the amine after hydrolysis of the isocyanate. In Entry 2, the dihydrazide intermediate is isolated as a solid and diazotized in aqueous solution, from which the amine is isolated as the dihydrochloride. Entry 3 is an example of the mixed anhydride procedure (see p. 948). The first stage of the reaction is carried out in acetone and the thermolysis of the acyl azide is done in refluxing toluene. The crude isocyanate is then hydrolyzed in acidic water. Entry 4 is a reaction that demonstrates the retention of configuration during rearrangement.

Entries 5 to 8 are synthetic applications in more complex molecules. Entries 5 and 6 illustrate the diphenylphosphoroyl azide method. Entry 7 was used in the late stages of the synthesis of an antitumor macrolide, zampanolide, to introduce the amino group. The ultimate target molecule in Entry 8 is himandrine, one of several polycyclic alkaloids isolated from an ancient plant species.

Section B shows some Hofmann rearrangements. Entry 9, using basic conditions with bromine, provided an inexpensive route to an intermediate for a commercial synthesis of an herbicide. Entry 10, which uses the $\text{Pb}(\text{OAc})_4$ conditions (see p. 949), was utilized in an enantiospecific synthesis of the naturally occurring analgesic (–)-epibatidine. Entry 11 uses phenyliodonium diacetate as the reagent. The product is the result of cyclization of the intermediate isocyanate and was used in an enantioselective synthesis of the antianxiety drug (*R*)-fluoxetine.

Entries 12 and 13 also involve cyclization of the isocyanate intermediates.

Section C of Scheme 10.15 shows some Schmidt reactions. Entry 14 is a procedure using polyphosphoric acid, whereas Entry 15 was done in H_2SO_4 . Entry 16 is a case of conversion of a cyclic ketone, adamantanone, to the corresponding lactam.

Section D shows some representative Beckmann rearrangements. Entry 17 shows a selective migration of a *t*-butyl group and illustrates the use of oxime sulfonates to control regioselectivity. The opposite regioisomer, resulting from migration of the phenyl group, was observed using HCl in acetic acid. Entry 18 illustrates another aspect of the stereochemistry of the Beckmann rearrangement. As shown, use of the benzenesulfonate led to retention of the *cis* ring juncture. When the reaction was done in H_2SO_4 or polyphosphoric acid, the *trans* isomer was formed, presumably as the result of fragmentation to a tertiary carbocation.

Entries 19 and 20 are examples of lactam formation by ring expansion of cyclic oximes.

10.3. Reactions Involving Free Radical Intermediates

The fundamental mechanisms of free radical reactions were considered in Chapter 11 of Part A. Several mechanistic issues are crucial in development of free radical reactions for synthetic applications.²⁸⁵ Free radical reactions are usually chain processes, and the lifetimes of the intermediate radicals are very short. To meet the synthetic requirements of high selectivity and efficiency, all steps in a desired sequence must be fast in comparison with competing reactions. Owing to the requirement that all the steps be fast, only steps that are exothermic or very slightly endothermic can participate in chain processes. Comparison between addition of a radical to a carbon-carbon double bond and addition to a carbonyl group can illustrate this point.

This comparison suggests that of these two similar reactions, only alkene additions are likely to be a part of an efficient radical chain sequence. Radical additions to carbon-carbon double bonds can be further enhanced by radical stabilizing groups. Addition to a carbonyl group, in contrast, is endothermic. In fact, the reverse fragmentation reaction is commonly observed (see Section 10.3.6). A comparison can also be made between abstraction of hydrogen from carbon as opposed to oxygen.

The reaction endothermicity establishes a *minimum* for the activation energy; whereas abstraction of a hydrogen atom from carbon is a feasible step in a chain process, abstraction of a hydrogen atom from a hydroxyl group is unlikely. Homolytic cleavage of an O—H bond is likely only if the resulting oxygen radical is stabilized, such as in phenoxy radicals formed from phenols.

²⁸⁵ C. Walling, *Tetrahedron*, **41**, 3887 (1985).

There is a good deal of information available about the absolute rates of free radical reactions. A selection from these data is given in Table 11.3 of Part A. If the steps in a projected reaction sequence correspond to reactions for which absolute rates are known, this information can allow evaluation of the kinetic feasibility of the reaction sequence.

10.3.1. Sources of Radical Intermediates

There is a discussion of some of the sources of radicals for mechanistic studies in Section 11.1.4 of Part A. Some of the reactions discussed there, particularly the use of azo compounds and peroxides as initiators, are also important in synthetic chemistry. One of the most useful sources of free radicals in preparative chemistry is the reaction of halides with stannyl radicals. Stannanes undergo hydrogen abstraction reactions and the stannyl radical can then abstract halogen from the alkyl group. For example, net addition of an alkyl group to a reactive double bond can follow halogen abstraction by a stannyl radical.

This generalized reaction sequence consumes the halide, the stannane, and the reactant X=Y , and effects addition to the organic radical and a hydrogen atom to the X=Y bond. The order of reactivity of organic halides toward stannyl radicals is iodides > bromides > chlorides.

Esters of *N*-hydroxypyridine-2-thione are another versatile source of radicals,²⁸⁶ where the radical is formed by decarboxylation of an adduct formed by attack at sulfur by the chain-carrying radical.²⁸⁷ The generalized chain sequence is as follows.

When X-Y is $\text{R}_3\text{Sn-H}$ the net reaction is decarboxylation and reduction of the original acyloxy group. Halogen atom donors can also participate in such reactions.

²⁸⁶. D. Crich, *Aldrichimica Acta*, **20**, 35 (1987); D. H. R. Barton, *Aldrichimica Acta*, **23**, 3 (1990).

²⁸⁷. D. H. R. Barton, D. Crich, and W. B. Motherwell, *Tetrahedron*, **41**, 3901 (1985); D. H. R. Barton, D. Crich, and G. Kretzschmar, *J. Chem. Soc., Perkin Trans. 1*, 39 (1986); D. H. R. Barton, D. Bridson, I. Fernandez-Picot, and S. Z. Zard, *Tetrahedron*, **43**, 2733 (1987).

When X–Y is $\text{Cl}_3\text{C}–\text{Cl}$, the final product is a chloride.²⁸⁸ Use of $\text{Cl}_3\text{C}–\text{Br}$ gives the corresponding bromide.²⁸⁹

The precise reaction conditions for optimal yields depend upon the specific reagents and both thermal²⁹⁰ and photochemical²⁹¹ conditions have been developed. Phenyl thionocarbonates are easily prepared and are useful in radical generating reactions.²⁹² A variety of other thiono esters, including xanthates and imidazolyl thiocarbonates also can be used.²⁹³

Selenyl groups can be abstracted by stannyl radicals from alkyl and acyl selenides to generate the corresponding radicals.²⁹⁴ Among the types of compounds that react by selenyl transfer are α -selenylphosphonates²⁹⁵ and α -selenylcyanides.²⁹⁶ The radicals generated can undergo addition and/or cyclization. The chain reaction is propagated by abstraction of hydrogen from the stannane.

Trialkylboranes, especially triethylborane, are used in conjunction with O_2 to generate radicals.²⁹⁷ The alkyl radicals are generated by breakdown of a borane-oxygen adduct. An advantage this method has over many other radical initiation systems is that it proceeds at low temperature, e.g., -78°C .

²⁹⁷ C. Ollivier and P. Renaud, *Chem. Rev.*, **101**, 3415 (2001).

The radicals generated in this way can initiate a variety of chain processes. Alkyl radicals can be generated from alkyl iodides.²⁹⁸ For example, addition of alkyl radicals to alkynes can be accomplished under these conditions.

Ref. 299

These reactions result in *iodine atom transfer* and introduce a potential functional group into the product. The trialkylborane method of radical generation can also be used in conjunction with either tri-*n*-butyl stannane or *tris*-(trimethylsilyl)silane, in which case the product is formed by hydrogen atom transfer.

The reductive decomposition of alkylmercury compounds is also a useful source of radicals.³⁰⁰ The organomercury compounds are available by oxymercuration (see Section 4.1.3) or from organometallic compounds as a result of metal-metal exchange (see Section 7.3.3).

Alkylmercury reagents can also be prepared from alkyl boranes.

Ref. 301

The mercuric hydride formed by reduction undergoes chain decomposition to generate alkyl radicals.

10.3.2. Addition Reactions of Radicals with Substituted Alkenes

The most general method for formation of new carbon-carbon bonds via radical intermediates involves addition of the radical to an alkene. The reaction generates a new radical that can propagate a chain sequence. The preferred alkenes for trapping alkyl

²⁹⁸ H. C. Brown and M. M. Midland, *Angew. Chem. Int. Ed. Engl.*, **11**, 692 (1972); K. Nozaki, K. Oshima, and K. Utimoto, *Tetrahedron Lett.*, **29**, 1041 (1988).

³⁰¹ R. C. Larock and H. C. Brown, *J. Am. Chem. Soc.*, **92**, 2467 (1976).

radicals are ethene derivatives with electron-attracting groups, such as cyano, ester, or other carbonyl substituents.³⁰² There are three factors that make such compounds particularly useful: (1) alkyl radicals are relatively *nucleophilic* and react at enhanced rates with alkenes having EWG substituents; (2) alkenes with such substituents exhibit a good degree of regioselectivity, resulting from a combination of steric and radical-stabilizing effects of the substituent; (3) the EWG substituent makes the adduct radical *more electrophilic* and increases the rate of the subsequent hydrogen abstraction step. The “nucleophilic” versus “electrophilic” character of radicals can be understood in terms of the FMO description of substituent effects on radicals. The three most important cases are outlined in Figure 10.12. An ERG in the radical raises the energy of the SOMO, which increases the stabilizing interaction with the LUMO of alkenes having EWG substituents. In the opposite combination, an EWG substituent on the radicals lowers the SOMO and the strongest interaction is with the alkene HOMO. This interaction is stabilizing because of lowering of the alkene HOMO.

Radicals for addition reactions can be generated by halogen atom abstraction by stannyl radicals. The chain mechanism for alkylation of alkyl halides by reaction with a substituted alkene is outlined below. There are three reactions in the propagation cycle of this chain mechanism: addition, hydrogen atom abstraction, and halogen atom transfer.

The rates of each of these steps must exceed competing chain termination reactions in order for good yields to be obtained. The most important competitions are between: (a) the addition step k_1 and reaction of the intermediate $R\cdot$ with Bu_3SnH , and (b) between the H abstraction step k_2 and addition to another molecule of the alkene. If

Fig. 10.12. Frontier orbital interpretation of radical substituent effects.

³⁰² B. Giese, *Angew. Chem. Int. Ed. Engl.*, **22**, 753 (1983); B. Giese, *Angew. Chem. Int. Ed. Engl.*, **24**, 553 (1985).

the addition step k_1 is not fast enough, the radical R^\cdot will abstract H from the stannane and the overall reaction will simply be dehalogenation. If step k_2 is not fast relative to a successive addition step, formation of oligomers containing several alkene units will occur. For good yields R^\cdot must be more reactive to the substituted alkene than is $RCH_2C^\cdot HZ$ and $RCH_2C^\cdot HZ$ must be more reactive toward Bu_3SnH than is R^\cdot . These requirements are met when Z is an electron-attracting group. Yields are also improved if the concentration of Bu_3SnH is kept low to minimize the reductive dehalogenation, which can be done by adding the stannane slowly as the reaction proceeds. Another method is to use only a small amount of the trialkyltin hydride along with a reducing agent, such as $NaBH_4$ or $NaBH_3CN$, that can regenerate the reactive stannane.³⁰³ Radicals formed by fragmentation of thionocarbonates and related thiono esters can also be trapped by reactive alkenes. The mechanism of radical generation from thiono esters was discussed in connection with the Barton deoxygenation method in Section 5.5.

Although most radical reactions involving chain propagation by hydrogen atom transfer can be done using trialkylstannanes, several silanes have been investigated as alternatives.³⁰⁴ *Tris*-(trimethylsilyl)silane reacts with alkyl radicals at about one-tenth the rate of tri-*n*-butylstannane. The *tris*-(trimethylsilyl)silyl radical is reactive toward iodides, sulfides, selenides, and thiono esters, permitting chain transfer. Thus it is possible to substitute *tris*-(trimethylsilyl)silane for tri-*n*-butylstannane in reactions such as dehalogenations, radical additions, and cyclizations. A virtue of the silane donors is that they avoid the tin-containing by-products of stannane reactions that can cause purification problems.

Alkyl radicals generated by reduction of organomercury compounds can also add to alkenes having EWG groups. Radicals are generated by reduction of the organomercurial by $NaBH_4$ or a similar reductant. These techniques have been

applied to β -hydroxy-,³⁰⁷ β -alkoxy-,³⁰⁸ and β -amido-³⁰⁹ alkylmercury derivatives. α -Acetoxyalkylmercury compounds can be prepared from hydrazones by mercuric oxide and mercuric acetate.

Ref. 310

Several other examples of addition reactions involving organomercury compounds are given in Section B of Scheme 10.16 at the end of this section.

There are also reactions in which electrophilic radicals react with relatively nucleophilic alkenes. These reactions are exemplified by a group of procedures in which a radical intermediate is formed by oxidation of readily enolizable compounds. This reaction was initially developed for β -ketoacids,³¹¹ and the method has been extended to β -diketones, malonic acids, and cyanoacetic acid.³¹² The radicals formed by the addition step are rapidly oxidized to cations, which give rise to the final product by intramolecular capture of a carboxylate group.

Phenacyl radicals can be generated from the corresponding xanthates and add in good yield to various substituted propenes. The products of the reaction can then be cyclized to tetralones using an equivalent of a peroxide.³¹³

This methodology has been applied to carbohydrate derivatives and provides a route to certain C-aryl glycosides.

Ref. 314

Scheme 10.16 gives some examples of radical addition reactions. Entry 1 is a typical alkylation reaction using Bu_3SnH as the chain carrier and hydrogen atom donor. The reaction was done at 100°C in toluene by slow (syringe pump) addition of one equivalent of Bu_3SnH . Five equivalents of methyl acrylate was used. Entry 2 utilized in situ generation of Bu_3SnH . This carbohydrate-derived bromide could not be added successfully to acrylonitrile or methyl acrylate under standard conditions. A tenfold excess of phenyl vinyl sulfone was used. In Entry 3, a carbohydrate-derived acrylate is the reactant. The stannane was added by syringe pump and a 20-fold excess of the iodoacetamide was used. In Entry 4, the unprotected carbohydrate hydroxy group was converted to a xanthate ester and then added to acrylonitrile. The stereoselectivity is determined by conformational factors that establish a preference for the direction of reagent approach. Radicals with a large bias can give highly stereoselective reactions.

Entry 5 is an example of the use of *tris*-(trimethylsilyl)silane as the chain carrier. Entries 6 to 11 show additions of radicals from organomercury reagents to substituted alkenes. In general, the stereochemistry of these reactions is determined by reactant conformation and steric approach control. In Entry 9, for example, addition is from the *exo* face of the norbornyl ring. Entry 12 is an example of addition of an acyl radical from a selenide. These reactions are subject to competition from decarbonylation, but the relatively slow decarbonylation of aroyl radicals (see Part A, Table 11.3) favors addition in this case.

Allylic stannanes are an important class of compounds that undergo substitution reactions with alkyl radicals. The chain is propagated by elimination of the trialkylstannyl radical.³¹⁵ The radical source must have some functional group that can be abstracted by trialkylstannyl radicals. In addition to halides, both thiono esters³¹⁶ and selenides³¹⁷ are reactive.

Allyl tris-(trimethylsilyl)silane can react similarly.³¹⁸

Allylation reactions can be initiated by triethylboron. This procedure has been found to give improved stereoselectivity in acyclic allylations.³¹⁹

Scheme 10.17 illustrates allylation by reaction of radical intermediates with allyl stannanes. The first entry uses a carbohydrate-derived xanthate as the radical source. The addition in this case is highly stereoselective because the shape of the bicyclic ring system provides a steric bias. In Entry 2, a primary phenylthiocarbonate ester is used as the radical source. In Entry 3, the allyl group is introduced at a rather congested carbon. The reaction is completely stereoselective, presumably because of steric features of the tricyclic system. In Entry 4, a primary selenide serves as the radical source. Entry 5 involves a tandem alkylation-allylation with triethylboron generating the ethyl radical that initiates the reaction. This reaction was done in the presence of a Lewis acid, but lanthanide salts also give good results.

These reactions exhibit excellent diastereoselectivity derived from the chiral oxazolidinone auxiliary. The Lewis acid forms a chelate with the oxazolidinone and presumably also serves to enhance reactivity. In addition to ethyl, other primary, secondary, and tertiary alkyl radicals, as well as acetyl and benzoyl radicals were used successfully in analogous reactions.

10.3.3. Cyclization of Free Radical Intermediates

Cyclization of radical intermediates is an important method for ring synthesis.³²⁰ The key step involves addition of a radical center to an unsaturated functional group. Many of these reactions involve halides as the source of the radical intermediate. The radicals are normally generated by halogen atom abstraction using a trialkylstannane as the reagent and AIBN as the initiator. The cyclization step must be fast relative to hydrogen abstraction from the stannane. The chain is propagated when the cyclized radical abstracts hydrogen from the stannane.

From a synthetic point of view, the regioselectivity and stereoselectivity of the cyclization are of paramount importance. As discussed in Section 11.2.3.3 of Part A, the order of preference for cyclization of alkyl radicals is 5-*exo* > 6-*endo*; 6-*exo* > 7-*endo*; 8-*endo* > 7-*exo* because of stereoelectronic preferences. For relatively rigid cyclic structures, proximity and alignment factors determined by the specific geometry of the ring system are of major importance. Theoretical analysis of radical addition indicates that the major interaction of the attacking radical is with the alkene LUMO.³²¹ The preferred direction of attack is not perpendicular to the π system, but rather at an angle of about 110°.

Figure 10.13 shows the preferred geometries and calculated energy differences based on MM2 modeling.

Another major influence on the direction of cyclization is the presence of substituents. Attack at a less hindered position is favored by both steric effects and the stabilizing effect that most substituents have on a radical center. These have been examined by DFT (UB3LYP/6-31+G**) calculations, and the results for 5-hexenyl radicals are shown in Figure 10.14. For the unsubstituted system, the 5-*exo* chair TS is favored over the 6-*endo* chair by 2.7 kcal/mol. A 5-methyl substituent disfavors the 5-*exo* relative to the 6-*endo* mode by 0.7 kcal/mol, whereas a 6-methyl substituent increases the preference for the 5-*exo* TS to 3.3 kcal/mol.³²²

This reaction has subsequently been used in a number of other cases.³²⁴ The five-membered rings are usually fused in a *cis* manner, minimizing strain. When cyclization is followed by hydrogen abstraction, the hydrogen atom is normally delivered from the less hindered side of the molecule. The following example illustrates these generalizations. The initial tetrahydrofuran ring closure gives the *cis*-fused ring. The subsequent hydrogen abstraction is from the less hindered axial direction.³²⁵

³²⁴. X. J. Salom-Roig, F. Denes, and P. Renaud, *Synthesis*, 1903 (2004).

³²⁵. M. J. Begley, H. Bhandal, J. H. Hutchinson, and G. Pattenden, *Tetrahedron Lett.*, **28**, 1317 (1987).

Reaction conditions have been developed in which the cyclized radical can react in some manner other than hydrogen atom abstraction. One such reaction is an iodine atom transfer. The cyclization of 2-iodo-2-methyl-6-heptyne is a structurally simple example.

Ref. 326

In this reaction, the trialkylstannane serves to initiate the chain sequence but it is present in low concentration to minimize the rate of hydrogen atom abstraction from the stannane. Under these conditions, the chain is propagated by iodine atom abstraction.

The fact that the cyclization is directed toward an acetylenic group and leads to formation of an alkenyl radical is significant. Formation of a saturated iodide could lead to a more complex product mixture because the cyclized product could undergo iodine atom transfer and proceed to add to a second unsaturated center. Vinyl iodides are much less reactive and the reaction product is unreactive. Owing to the potential

³²⁶ D. P. Curran, M.-H. Chen, and D. Kim, *J. Am. Chem. Soc.*, **108**, 2489 (1986); D. P. Curran, M.-H. Chen, and D. Kim, *J. Am. Chem. Soc.*, **111**, 6265 (1989).

for competition from reduction by the stannane, other reaction conditions have been developed to promote cyclization. Hexabutyliditin can be used.³²⁷

Alkenyl radicals generated by addition of trialkylstannyl radicals to terminal alkynes can undergo cyclization with a nearby double bond.

Ref. 328

The addition of a vinyl radical to a double bond is usually favorable thermodynamically because a more stable alkyl radical is formed. The vinyl radical can be generated by dehalogenation of vinyl bromides or iodides. An early study provided examples of both five- and six-membered rings being formed.³²⁹ The six-membered ring is favored when a branching substituent is introduced.

An alternative system for initiating radical cyclization uses triethylborane and oxygen. Under these conditions, *tris*-(trimethylsilyl)silane is an effective hydrogen donor.³³⁰

³²⁷ D. P. Curran and J. Tamine, *J. Org. Chem.*, **56**, 2746 (1991).

³²⁸ G. Stork and R. Mook, Jr., *J. Am. Chem. Soc.*, **109**, 2829 (1987).

These cyclizations can also be carried out without a hydrogen donor, in which case the chain is propagated by iodine atom transfer.³³¹ If necessary, ethyl iodide can be added to facilitate iodine atom transfer.

Ref. 332

Intramolecular additions have also been accomplished using xanthate and thiono-carbonates.

Ref. 333

When a hydrogen donor is present, the product results from reduction.

Ref. 334

Cyclization of both alkyl and acyl radicals generated by selenide abstraction have also been observed.

Triethylborane can also be used for radical initiation and the low temperature can lead to improved yields and stereoselectivity.

Ref. 330b

10.3.4. Additions to C=N Double Bonds

Several functional groups containing carbon-nitrogen double bonds can participate in radical cyclizations. Among these are oxime ethers, imines, and hydrazones.³³⁷ Hydrazones and oximes are somewhat more reactive than imines, evidently because the adjacent substituents can stabilize the radical center at nitrogen.³³⁸ Cyclization at these functional groups leads to amino- substituted products.

Ref. 339

Ref. 340

Ref. 341

A radical cyclization of this type was used to synthesize the 4-amino-5-hydroxyhexahydroazepine group found in the PKC inhibitor balanol. The cyclization involves an α -stannyloxy radical formed by addition of the stannyl radical to the aldehyde oxygen.

Ref. 342

The reactivity of oxime ethers as radical acceptors is enhanced by Lewis acids, BF_3 being the most effective.³⁴³

Addition to oxime ethers of glyoxylic acid generates *N*-benzyloxyamino acids. These reactions have been done in both organic solvents³⁴⁴ and aqueous mixtures.³⁴⁵ The reactions can be done with or without Bu_3SnH as a chain carrier.

Scheme 10.18 gives some additional examples of cyclization reactions involving radical intermediates. Section A pertains to reactions of alkyl halides. Entry 1 is an early example of the application of a radical cyclization and was used in the synthesis of the terpenes sativene and copacamphene. Entry 2 is an example of the use of the β -bromo- α -ethoxyethyl group in radical cyclization. Ring strain effects dictate the formation of the *cis*-fused five-membered ring, and the stereochemistry of the decalin ring junction is then controlled by the shape of the tricyclic radical intermediate, resulting in good stereochemical control. Entry 3 involves addition of an alkenyl radical. Entry 4 involves generation of a vinyl radical that undergoes stereoequilibration faster than cyclization. The 6-*endo* mode of cyclization is favored by both steric and radical stabilization effects. Entry 5 is an 5-*exo* cyclization. Several similar reactions showed a preference of about 8:1 for generation of the *anti* stereochemical relationship at the two new stereocenters. Another noteworthy feature of this reaction is the successful reaction between a relatively electrophilic radical and the acrylate moiety. Entry 6 has several interesting aspects. The reaction proceeds by iodine atom transfer and the cyclization mode is 9-*endo*. The initiation is by triethylborane and the reaction gives much higher yields in water than in benzene. The efficiency of the cyclization and the solvent sensitivity are probably related to reactant conformation. Entry 7 is another iodine atom transfer cyclization initiated by triethylboron. Entry 8 involves 5-*exo* addition to an alkynylsilane.

Section B of Scheme 10.18 shows examples of the use of sulfides, thiono esters, and selenides as radical sources. The imidazolyl thionocarbamate group used in Entry 9 is one of the thioester groups developed as a source of radicals. In this particular reaction, the phenylthionocarbonate group is even more effective. The ring closure generates an *anti* relationship between the benzyloxy and methoxymethyl substituents. This stereochemistry is consistent with a boatlike TS that may be preferred in order to maintain the preferred conformation of the dioxane ring while avoiding allylic strain in the side chain.

Entry 10 shows the occurrence of 5-*exo* cyclization. The radical in this case is generated from an amino sulfide. This reaction requires a specific, somewhat disfavored conformation of the reactant in order for cyclization to occur. When the unsubstituted vinyl substituent was used, no cyclization occurred. However, increasing the reactivity of the double bond by adding the ester substituent led to successful cyclization.

Entry 11 involves generation and cyclization of an alkoxyethyl radical from a selenide. The cyclization mode is the anticipated 5-*exo* with a *cis* ring juncture. This is a case in which the electronic characteristics of the radical are not particularly favorable (ERG oxygen in the radical), but cyclization nevertheless proceeds readily. The reaction in Entry 12 was used to prepare a precursor of epibatidine. Entry 13 shows a 6-*endo* cyclization that is favored by steric factors. The 6-*endo* cyclization is also favored with a tetrahydropyranyloxy substituent in place of the ester, indicating that the electronic effect is not important. Entries 14 to 16 involve acyl radicals generated from selenides. The preferred 6-*endo* cyclization in Entry 15 is thought to be due to the preference for the less-substituted end of the double bond. Entry 17 is an example of a 5-*exo-dig* cyclization.

Entries 18 to 19 pertain to cyclizations of electrophilic radicals generated by oxidations. Entry 18 is the prototype for cyclization of a number of more highly substituted systems. The reaction outcome is consistent with oxidation of the less-substituted enolic position followed by a 6-*endo* cyclization. The cyclized radical is then oxidized and deprotonated. In Entry 19, the vinyl radical formed by cyclization is reduced by hydrogen abstraction from the solvent ethanol.

Entries 20 to 23 involve additions to C=N double bonds in oxime ethers and hydrazones. These reactions result in installation of a nitrogen substituent on the newly formed rings. Entry 20 involves the addition of the triphenylstannyl radical to the terminal alkyne followed by cyclization of the resulting vinyl radical. The product can be proto-destannylated in good yield. The ring closure generates an *anti* relationship for the amino substituent, which is consistent with the TS shown below.

Entry 21 involves addition to a glyoxylic hydrazone and the *cis* ring junction is dictated by strain effects. The primary phenylselenenyl group is reductively removed under the reaction conditions. Entry 22 involves generation of a stannyloxy radical by addition of the stannyl radical at the carbonyl *oxygen*. Cyclization then ensues, with the *cis-trans* ratio being determined by the conformation of the cyclization TS.

Entry 23 was part of a synthesis of the pancratistatin structure. The lactone ring was used to control the stereochemistry at the cyclization center. Noncyclic analogs gave a mixture of stereoisomers at this center. In this reaction, triphenylstannane gave much better yields than tri-*n*-butylstannane.

10.3.5. Tandem Radical Cyclizations and Alkylations

The synthetic scope of radical cyclizations can be further extended by tandem trapping by electrophilic alkene.

Ref.346

Alkenyl radicals generated by intramolecular addition to a triple bond can add to a nearby double bond, resulting in a tandem cyclization process.

Ref. 347

³⁴⁶. G. Stork and P. M. Sher, *J. Am. Chem. Soc.*, **108**, 303 (1986).

³⁴⁷. G. Stork and R. Mook, Jr., *J. Am. Chem. Soc.*, **105**, 3720 (1983).

As with carbocation-initiated polyene cyclizations, radical cyclizations can proceed through several successive steps if the steric and electronic properties of the reactant provide potential reaction sites. Cyclization may be followed by a second intramolecular step or by an intermolecular addition or alkylation. Intermediate radicals can be constructed so that hydrogen atom transfer can occur as part of the overall process. For example, 2-bromohexenes having radical stabilizing substituents at C(6) can undergo cyclization after a hydrogen atom transfer step.³⁴⁸

The success of such reactions depends on the intramolecular hydrogen transfer being faster than hydrogen atom abstraction from the stannane reagent. In the example shown, hydrogen transfer is favored by the thermodynamic driving force of radical stabilization, by the intramolecular nature of the hydrogen transfer, and by the steric effects of the central quaternary carbon. This substitution pattern often favors intramolecular reactions as a result of conformational effects.

This type of cyclization has also been carried out using thiophenol to generate the reactive radicals. Good yields were obtained for both EWG and ERG substituents.³⁴⁹

Scheme 10.19 gives some other examples of tandem radical reactions. Entry 1 was used to construct the disubstituted cyclopentane system found in the prostaglandins. The first 5-*exo* cyclization to generate the tetrahydrofuran ring is followed by intermolecular trapping of the radical by the α -(trimethylsilyl)enone. In Entry 2, a primary radical was generated and adds to the cyclopentene, generating a tertiary radical that adds to the terminal alkyne. Both ring junctions are *cis*. In Entry 3, a reactive radical is generated from the xanthate groups, and it adds to the styrene double bond faster than

In Entry 4, the initial cyclization is evidently a 5-*endo* process, which in this case is strongly favored by the substitution pattern (captor-dative substituents; see Part A, Section 11.1.6). Most of the cyclized radical then undergoes addition to the cyclohexene ring, generating the major product. In this step, the 6-*endo* process is favored both thermodynamically (5,6- versus 5,5-ring fusion) and by the less-substituted nature of the double bond in this mode. Entry 5 illustrates creation of a CD fragment of the steroid ring system, with side chains in place to create the B ring. The stereochemistry at the ring junction and substitution sites was highly selective. Entry 6 involves a 5-*exo* cyclization followed by a 6-*endo-dig* cyclization. It was found that the selectivity of the tandem sequence was improved by the trimethylsilyl substituent. Entry 7 was used in the synthesis of the carbon skeleton of the terpene modhephene. The sequence consists of two 5-*exo* cyclizations, the first of which is transannular. In Entry 8, the first step is a 5-*exo* cyclization of a bromoacetaldehyde acetal. This is followed by a 7-*endo* cyclization that is favored by the steric and substituent effects of the isopropenyl group. The hydrogen abstraction at the terminal tertiary radical site is highly stereoselective because of ring geometry.

In Entry 9, the initial reaction involves 5-*exo* addition of the aryl radical to the more-substituted end of the cyclohexene double bond, followed by a 6-*endo* addition to the phenylthiovinyl group. The reaction is completed by elimination of the phenylthio radical. The product is an intermediate in the synthesis of morphine.

Entries 10 to 12 are examples of oxidative generation of radicals, followed by tandem cyclization. The reaction in Entry 10 includes a lanthanide catalyst. Entry 11

results in the formation of the *trans* decalin product. The by-products of this reaction suggest that the first cyclization is a radical reaction but that oxidation to the tertiary carbocation occurs prior to the second cyclization. Entry 12 involves a tandem process in which the intermediate radical is captured by the second double bond. The presence of Cu(II) results in oxidation of the cyclized radical to an alkene.

Entries 13 to 15 involve adding to carbon-nitrogen multiple bonds. The reaction in Entry 13 is initiated by addition of the stannyl radical to the terminal alkyne. Cyclization generates a primary radical that adds to the cyano group. Cyano groups are not particularly good radical traps, but in this case the group is in close proximity to the radical center. The imine formed by the addition is hydrolyzed and the vinylstannane undergoes proto-destannylation on exposure to silica. In Entry 14, a vinyl radical is generated by thiyl radical addition, followed by cyclization with the oximino ether. Entry 15 involves generation of an aryl radical using the triethylborane system. The low temperature available under these conditions results in much higher stereoselectivity at the acetate side chain than the reaction initiated by a stannyl radical.

10.3.6. Fragmentation and Rearrangement Reactions

Fragmentation is the reverse of radical addition. Fragmentation of radicals is often observed to be fast when the overall transformation is exothermic.

The fragmentation of alkoxy radicals is especially favorable because the formation of a carbonyl bond makes such reactions exothermic. Rearrangements of radicals frequently occur by a series of addition-fragmentation steps. The following two reactions involve radical rearrangements that proceed through addition-elimination sequences.

Ref. 350

³⁵⁰ P. Dowd and S.-C. Choi, *J. Am. Chem. Soc.*, **109**, 6548 (1987).

Ref. 352

Both of these transformations feature addition of a carbon-centered radical to a carbonyl group, followed by fragmentation to a more stable radical. The rearranged radical then abstracts hydrogen from the co-reactant $n\text{-Bu}_3\text{SnH}$. The addition step must be fast relative to hydrogen abstraction because if this is not the case, simple reductive dehalogenation will occur. The fragmentation step is usually irreversible for two reasons: (1) the reverse addition is endothermic; (2) the product radical is substituted by the electron-withdrawing alkoxy carbonyl group and is unreactive to addition to carbonyl bonds.

The two reactions above are examples of a more general reactivity pattern.³⁵¹

The unsaturated group $X=Y$ that is formally “transferred” by the rearrangement process can be $C=C$, $C=O$, $C=N$, or any other group that fulfills the following general criteria: (1) the addition step **a** must be fast relative to other potentially competing reactions; and (2) the group Z must stabilize the product radical so that the overall process is energetically favorable. A direct comparison of the ease with which unsaturated groups migrate by cyclization-fragmentation has been made for the case of 1,2-migration.

In this system, the overall driving force is the conversion of a primary radical to a tertiary one ($\Delta H \sim -5 \text{ kcal}$) and the activation barrier incorporates strain associated with formation of the three-membered ring. Rates and activation energies for several migrating groups were determined.³⁵² A noteworthy feature is the low reactivity of

^{351.} (a) A. L. J. Beckwith, D. M. O'Shea, and S. W. Westwood, *J. Am. Chem. Soc.*, **110**, 2565 (1988);
(b) R. Tsang, J. K. Pickson, Jr., H. Pak, R. Walton, and B. Fraser-Reid, *J. Am. Chem. Soc.*, **109**, 3484 (1987).

^{352.} D. A. Lindsay, J. Luszyk, and K. U. Ingold, *J. Am. Chem. Soc.*, **106**, 7087 (1984).

alkyne and cyano groups, which is due to the additional strain introduced in the three-membered ring by the sp^2 carbon. Aryl groups are also relatively unreactive because of the loss of aromaticity in the cyclic intermediate.

X=Y					
					
k_r (s^{-1})	10^7	1.7×10^5	7.6×10^3	93	0.9
E_a (kcal/mol)	5.7	7.8	11.8	12.8	16.4

Among the most useful radical fragmentation reactions from a synthetic point of view are decarboxylations and fragmentations of alkoxy radicals. The use of *N*-hydroxy-2-thiopyridine esters for decarboxylation is quite general. Several procedures and reagents are available for preparation of the esters,³⁵³ and the reaction conditions are compatible with many functional groups.³⁵⁴ *t*-Butyl mercaptan and thiophenol can serve as hydrogen atom donors.

Ref. 355

Esters of *N*-hydroxyphthalimide can also be used for decarboxylation. Photolysis in the presence of an electron donor and a hydrogen atom donor leads to decarboxylation. Carboxyl radicals are formed by one-electron reduction of the phthalimide ring.

Ref. 356

Fragmentation of cyclopropylcarbinyl radicals has been incorporated into several synthetic schemes.³⁵⁷ For example, 2-dienyl-1,1-(dimethoxycarbonyl)-cyclopropanes undergo ring expansion to cyclopentenones.

³⁵³ F. J. Sardina, M. H. Howard, M. Morningstar, and H. Rapoport, *J. Org. Chem.*, **55**, 5025 (1990); D. Bai, R. Xu, G. Chu, and X. Zhu, *J. Org. Chem.*, **61**, 4600 (1996).

³⁵⁷ P. Dowd and W. Zhang, *Chem. Rev.*, **93**, 2091 (1993).

Ref. 358

These reactions presumably involve terminal addition of the chain-carrying radical, followed by fragmentation and recyclization.

Other intramolecular cyclizations can follow generation and fragmentation of cyclopropylcarbinyl radicals. In the example below, the fragmented radical adds to the alkyne.

Ref. 359

Cyclic α -halomethyl or α -phenylselenenylmethyl β -ketoesters undergo one-carbon ring expansion via transient cyclopropylalkoxy radicals.³⁶⁰

Comparable cyclization-fragmentation sequences have been developed for acyclic and heterocyclic systems.

Ref. 361

Ref. 362

Similar reactions can be conducted using *tris*-(trimethylsilyl)silane as the hydrogen atom donor.³⁶³

Fragmentation of alkoxy radicals finds use in construction of medium-size rings.³⁶⁴ One useful reagent combination is phenyliodonium diacetate and iodine.³⁶⁵ The radical formed by fragmentation is normally oxidized to the corresponding carbocation and trapped by iodide or another nucleophile.

This reagent also can cleave the C(1)–C(2) bond in furanose carbohydrates.

Ref. 366

When the 5-hydroxy group is unprotected, it can capture the fragmented intermediate.³⁶⁷

³⁶⁷ P. de Armas, C. G. Francisco, and E. Suarez, *J. Am. Chem. Soc.*, **115**, 8865 (1993).

Ref. 368

Similarly, bicyclic hemiacetals fragment to medium-size lactones.

Ref. 369

These reactions are believed to proceed through hypoiodite intermediates.

Alkoxy radical fragmentation is also involved in ring expansion of 3- and 4-haloalkyl cyclohexanones. The radical formed by halogen atom abstraction adds to the carbonyl group, after which fragmentation to the carboethoxy-stabilized radical occurs.³⁷⁰

The by-product results from competing reduction of the radical by hydrogen atom abstraction.

10.3.7. Intramolecular Functionalization by Radical Reactions

In this section we focus on intramolecular functionalization. Such reactions normally achieve selectivity on the basis of proximity of the reacting centers. In acyclic molecules, intramolecular functionalization normally involves hydrogen atom abstraction via a six-membered cyclic TS. The net result is introduction of functionality at the δ -atom in relation to the radical site.

³⁶⁸ M. Kaino, Y. Naruse, K. Ishihara, and H. Yamamoto, *J. Org. Chem.*, **55**, 5814 (1990).

³⁶⁹ J. Lee, J. Oh, S. Jin, J.-R. Choi, J. L. Atwood, and J. K. Cha, *J. Org. Chem.*, **59**, 6955 (1994).

³⁷⁰ P. Dowd and S.-C. Choi, *Tetrahedron*, **45**, 77 (1989); P. Dowd and S.-C. Choi, *J. Am. Chem. Soc.*, **109**, 6548 (1987).

One example of this type of reaction is the photolytically initiated decomposition of *N*-chloroamines in acidic solution, which is known as the *Hofmann-Loeffler-Freytag reaction*.³⁷¹ The initial products are δ -chloroamines, but these are usually converted to pyrrolidines by intramolecular nucleophilic substitution.

A closely related procedure results in formation of γ -lactones. Amides are converted to *N*-iodoamides by reaction with iodine and *t*-butyl hypochlorite. Photolysis of the *N*-iodoamides gives lactones via iminolactone intermediates.³⁷²

Steps similar to the Hofmann-Loeffler reaction are also involved in cyclization of *N*-alkylmethanesulfonamides by oxidation with $\text{Na}_2\text{S}_2\text{O}_4$ in the presence of cupric ion.³⁷³

There are also useful intramolecular functionalization methods that involve hydrogen atom abstraction by oxygen radicals. The conditions that were originally developed involved thermal or photochemical dissociation of alkoxy derivative of Pb(IV) generated by exchange with $\text{Pb}(\text{OAc})_4$.³⁷⁴ These decompose, giving alkoxy

³⁷⁴ K. Heusler, *Tetrahedron Lett.*, 3975 (1964).

radicals with reduction to Pb(III). The subsequent oxidation of the radical to a carbocation is effected by Pb(IV) or Pb(III).

Current procedures include iodine and are believed to involve a hypoiodite intermediate.³⁷⁵

Ref. 376

The reactions can also be effected by phenyliodonium diacetate.³⁷⁷ A mechanistic prototype can be found in the conversion of pentanol to 2-methyltetrahydrofuran. The secondary radical is most likely captured by iodine or oxidized to the carbocation prior to cyclization.³⁷⁸

Alkoxy radicals are also the active hydrogen-abstracting species in a procedure that involves photolysis of nitrite esters. This reaction was originally developed as a method for functionalization of methyl groups in steroids.³⁷⁹

It has found other synthetic applications.

Ref. 380

These reactions depend on the proximity of the alkoxy radical to a particular hydrogen for selectivity.

Problems

(References for these problems will be found on page 1287.)

10.1. Indicate the major product to be expected in the following reactions:

³⁸⁰. E. J. Corey, J. F. Arnett, and G. N. Widiger, *J. Am. Chem. Soc.*, **97**, 430 (1975).

10.2. Indicate appropriate reagents and reaction conditions or a short reaction sequence that could be expected to effect the following transformations:

10.3. Each of the following carbenes has been predicted to have a singlet ground state, either as the result of qualitative structural considerations or theoretical calculations. Indicate what structural features might stabilize the singlet state in each case.

- 10.4. The hydroxy group in *E*-cycloocten-3-ol determines the stereochemistry of the reaction with the Simmons-Smith reagent. By examining a model, predict the stereochemistry of the product.
- 10.5. Discuss the significance of the relationship between reactant stereochemistry and product composition exhibited in the reactions shown below.

- 10.6. Suggest a mechanistic rationalization for the following reactions. Point out the structural features that contribute to the unusual or abnormal course of the reaction. What product would have been expected if the reaction followed a “normal” course.

- 10.7. It has been found that the bromo ketones **10-7a-c** can rearrange by either the cyclopropanone or the semibenzilic mechanism, depending on the size of the ring and the reaction conditions. Suggest two experiments that would permit you to distinguish between the two mechanisms under a given set of circumstances.

10.8. Predict the major product of the following reactions:

10.9. Short reaction series can effect formation of the desired material on the left from the starting material on the right. Devise an appropriate reaction sequence.

10.10. Formulate mechanisms for the following reactions:

- 10.11. A sequence of reactions for conversion of acyclic and cyclic ketones into α,β -unsaturated ketones with insertion of a $=\text{CHCH}_3$ unit has been developed. The method uses 1-lithio-1,1-dichloroethane as a key carbenoid reagent. The overall sequence involves three steps, one of them before and one after the carbenoid reaction. By analysis of the bonding changes and application of your knowledge of carbene reactions, devise a reaction sequence that would accomplish the transformation.

- 10.12. The synthesis of globulol from the octalin derivative shown proceeds in four stages. These include, not necessarily in sequence, addition of a carbene, a fragmentation reaction, and acid-catalyzed cyclization of a cyclodeca-2,7-dienol. The final step of the synthesis converts a dibromocyclopropane to the dimethylcyclopropane structure using dimethylcuprate. Using retrosynthetic analysis, devise an appropriate sequence of reactions and suggest reagents for each step.

- 10.13. Both the *E*- and *Z*-isomers of vinylsilane **13-A** have been subjected to polyene cyclization using $\text{TiCl}_4\text{-Ti}(\text{O-}i\text{-Pr})_4$. Although the *Z*-isomer gives an 85–90% yield, the *E*-isomer affords only a 30–40% yield. Offer an explanation.

- 10.14. Each of the three decahydroquinoline sulfonates shown below gives a different product composition on solvolysis. One gives 9-methylamino-*E*-non-5-enal, one gives 9-methylamino-*Z*-non-5-enal, and one gives a mixture of the two quinoline derivatives **14-D** and **14-E**. Deduce which compound gives rise to which product. Explain your reasoning.

- 10.15. Normally, the dominant reaction between acyl diazo compounds and simple α,β -unsaturated carbonyl compounds is a cycloaddition.

If, however, the reaction is run in the presence of a Lewis acid, particularly SbF_5 , the reaction takes a different course, giving a diacyl cyclopropane.

Formulate a mechanism to account for the altered course of the reaction in the presence of SbF_5 .

- 10.16. Compound **16-A** on reaction with Bu_3SnH in the presence of AIBN gives **16-B** rather than **16-C**. How is **16-B** formed? Why is **16-C** not formed? What relationship do these results have to the rate data given on p. 986?

- 10.17. The following molecules have been synthesized by radical cyclization and tandem radical cyclizations. Identify the bond or bonds that could be formed by radical cyclizations and suggest an appropriate reactant and reaction conditions that would lead to the specified products.

- 10.18. Attempted deoxygenation of several β -aryl thiono carbonates gave the unexpected product shown. In contrast, the corresponding α -isomers gave the desired deoxygenation product. Account for the formation of the observed products, and indicate why these products are not formed from the α -stereoisomers.

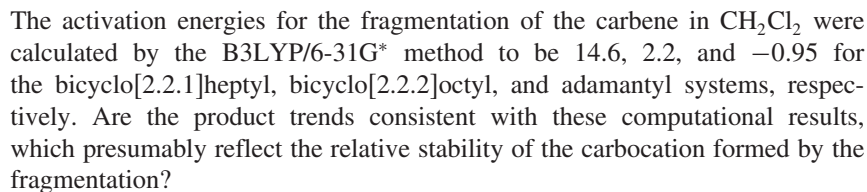

- 10.19. *cis*-Chrysanthemic acid has been synthesized through three intermediates using the reaction conditions shown. Assign structures to the intermediates and indicate the nature of each of the reactions.

- 10.20. The photolysis of alkoxy chlorodiazirines generates carbenes. The reaction has been examined in pentane and CH_2Cl_2 with increasing amounts of methanol. Three products, the bridgehead chloride, bridgehead ether, and bridgehead alcohol are formed. The former two products arise from fragmentation of the carbene. The last results from trapping of the carbene prior to fragmentation.

Aromatic Substitution Reactions

Introduction

This chapter is concerned with reactions that introduce or replace substituent groups on aromatic rings. The synthetic methods for aromatic substitution were among the first to be developed. The basic mechanistic concepts for electrophilic aromatic substitution and some of the fundamental reactions are discussed in Chapter 9 of Part A. These reactions provide methods for introduction of nitro groups, the halogens, sulfonic acids, and alkyl and acyl groups. The regioselectivity of these reactions depends upon the nature of the existing substituent and can be *ortho*, *meta*, or *para* selective.

A second group of aromatic substitution reactions involves aryl diazonium ions. As for electrophilic aromatic substitution, many of the reactions of aromatic diazonium ions date to the nineteenth century. There have continued to be methodological developments for substitution reactions of diazonium intermediates. These reactions provide routes to aryl halides, cyanides, and azides, phenols, and in some cases to alkenyl derivatives.

Direct nucleophilic displacement of halide and sulfonate groups from aromatic rings is difficult, although the reaction can be useful in specific cases. These reactions can occur by either addition-elimination (Section 11.2.2) or elimination-addition (Section 11.2.3). Recently, there has been rapid development of metal ion catalysis, and old methods involving copper salts have been greatly improved. Palladium catalysts for nucleophilic substitutions have been developed and have led to better procedures. These reactions are discussed in Section 11.3.

Several radical reaction have some synthetic application, including radical substitution (Section 11.4.1) and the $\text{S}_{\text{RN}}1$ reaction (Section 11.4.2).

11.1. Electrophilic Aromatic Substitution

The basic mechanistic concepts and typical electrophilic aromatic substitution reactions are discussed in Sections 9.1 and 9.4 of Part A. In the present section, we expand on that material, with particular emphasis on synthetic methodology.

11.1.1. Nitration

Nitration is the most important method for introduction of nitrogen functionality on aromatic rings. Nitro compounds can be reduced easily to the corresponding amino derivatives, which can provide access to diazonium ions. There are several reagent systems that are useful for nitration. A major factor in the choice of reagent is the reactivity of the ring to be nitrated. Nitration is a very general reaction and satisfactory conditions can normally be developed for both activated and deactivated aromatic compounds. Since each successive nitro group reduces the reactivity of the ring, it is easy to control conditions to obtain a mononitration product. If polynitration is desired, more vigorous conditions are used.

Concentrated nitric acid can effect nitration but it is not as reactive as a mixture of nitric acid with sulfuric acid. The active nitrating species in both media is the nitronium ion, NO_2^+ , which is formed by protonation and dissociation of nitric acid. The concentration of NO_2^+ is higher in the more strongly acidic sulfuric acid than in nitric acid.

Nitration can also be carried out in organic solvents, with acetic acid and nitromethane being common examples. In these solvents the formation of the NO_2^+ is often the rate-controlling step.¹

¹ E. D. Hughes, C. K. Ingold, and R. I. Reed, *J. Chem. Soc.*, 2400 (1950); J. G. Hoggett, R. B. Moodie, and K. Schofield, *J. Chem. Soc. B*, 1 (1969); K. Schofield, *Aromatic Nitration*, Cambridge University Press, Cambridge, 1980, Chap. 2.

Another useful medium for nitration is a solution prepared by dissolving nitric acid in acetic anhydride, which generates acetyl nitrate. This reagent tends to give high *ortho:para* ratios for some nitrations.²

A convenient procedure involves reaction of the aromatic in chloroform or dichloromethane with a nitrate salt and trifluoroacetic anhydride.³ Presumably trifluoroacetyl nitrate is generated under these conditions.

Acetic anhydride and trifluoroacetic anhydride have both been used in conjunction with nitric acid and zeolite β . This system give excellent *para* selectivity in many cases.⁴ The improved selectivity is thought to occur as a result of nitration within the zeolite pores, which may restrict access to the *ortho* position; see, e.g., Entry 7 in Scheme 11.1.

Nitration can be catalyzed by lanthanide salts. For example, the nitration of benzene, toluene, and naphthalene by aqueous nitric acid proceeds in good yield in the presence of $\text{Yb}(\text{O}_3\text{SCF}_3)_3$.⁵ The catalysis presumably results from an oxyphilic interaction of nitrate ion with the cation, which generates or transfers the NO_2^+ ion.⁶ This catalytic procedure uses a stoichiometric amount of nitric acid and avoids the excess strong acidity associated with conventional nitration conditions.

A variety of aromatic compounds can be nitrated using $\text{Sc}(\text{O}_3\text{SCF}_3)_3$, with LiNO_3 or $\text{Al}(\text{NO}_3)_3$ and acetic anhydride (see Scheme 11.1, Entry 9).⁷

Salts containing the nitronium ion can be prepared and are reactive nitrating agents. The tetrafluoroborate salt has been used most frequently,⁸ but the

⁸. S. J. Kuhn and G. A. Olah, *J. Am. Chem. Soc.*, **83**, 4564 (1961); G. A. Olah and S. J. Kuhn, *J. Am. Chem. Soc.*, **84**, 3684 (1962); G. A. Olah, S. C. Narang, J. A. Olah, and K. Lammertsma, *Proc. Natl. Acad. Sci., USA*, **79**, 4487 (1982); C. L. Dwyer and C. W. Holzapel, *Tetrahedron*, **54**, 7843 (1998).

trifluoromethanesulfonate can also be prepared readily.⁹ Nitrogen heterocycles such as pyridine and quinoline form *N*-nitro salts on reaction with NO_2BF_4 .¹⁰ These *N*-nitro heterocycles in turn can act as nitrating reagents, in a reaction called *transfer nitration* (see Scheme 11.1, Entry 10).

Another nitration procedure uses ozone and nitrogen dioxide.¹¹ With aromatic hydrocarbons and activated derivatives, this nitration is believed to involve the radical cation of the aromatic reactant.

Compounds such as phenylacetate esters and phenylethyl ethers, which have oxygen substituents that can serve as directing groups, show high *ortho:para* ratios under these conditions.¹² These reactions are believed to involve coordination of the NO_2^+ at the substituent oxygen, followed by intramolecular transfer.

Scheme 11.1 gives some examples of nitration reactions. Entries 1 to 3 are cases involving mixed nitric and sulfuric acids. Entry 2 illustrates the *meta*-directing effect of the protonated amino substituent. Entry 3 is an example of dinitration. Entry 4 involves an activated ring, and nitric acid suffices for nitration. At first glance, the position of substitution might seem surprising, but it may be that the direct resonance interaction of the 4-methoxy group with the formyl group attenuates its donor effect, leading to dominance of the 3-methoxy group.

Entry 5 is an example of nitration in acetic anhydride. An interesting aspect of this reaction is its high selectivity for the *ortho* position. Entry 6 is an example of the use of trifluoroacetic anhydride. Entry 7 illustrates the use of a zeolite catalyst with improved *para* selectivity. With mixed sulfuric and nitric acids, this reaction gives a 1.8:1 *para:ortho* ratio. Entry 8 involves nitration using a lanthanide catalyst, whereas Entry 9 illustrates catalysis by $\text{Sc}(\text{O}_3\text{SCF}_3)_3$. Entry 10 shows nitration done directly with $\text{NO}_2^+\text{BF}_4^-$, and Entry 11 is also a transfer nitration. Entry 12 is an example of the use of the $\text{NO}_2\text{—O}_3$ nitration method.

11.1.2. Halogenation

The introduction of the halogens onto aromatic rings by electrophilic substitution is an important synthetic procedure. Chlorine and bromine are reactive toward aromatic hydrocarbons, but Lewis acid catalysts are normally needed to achieve desirable rates. Elemental fluorine reacts very exothermically and careful control of conditions is required. Molecular iodine can effect substitution only on very reactive aromatics, but a number of more reactive iodination reagents have been developed.

Rate studies show that chlorination is subject to acid catalysis, although the kinetics are frequently complex.¹³ The proton is believed to assist Cl–Cl bond breaking in a reactant-Cl₂ complex. Chlorination is much more rapid in polar than in nonpolar solvents.¹⁴ Bromination exhibits similar mechanistic features.

¹³ L. M. Stock and F. W. Baker, *J. Am. Chem. Soc.*, **84**, 1661 (1962); L. J. Andrews and R. M. Keefer, *J. Am. Chem. Soc.*, **81**, 1063 (1959); R. M. Keefer and L. J. Andrews, *J. Am. Chem. Soc.*, **82**, 4547 (1960); L. J. Andrews and R. M. Keefer, *J. Am. Chem. Soc.*, **79**, 5169 (1957).

¹⁴ L. M. Stock and A. Himoe, *J. Am. Chem. Soc.*, **83**, 4605 (1961).

For preparative reactions, Lewis acid catalysts are used. Zinc chloride or ferric chloride can be used in chlorination, and metallic iron, which generates ferric bromide, is often used in bromination. The Lewis acid facilitates cleavage of the halogen-halogen bond.

N-Bromosuccinimide (NBS) and *N*-chlorosuccinimide (NCS) are alternative halogenating agents. Activated aromatics, such as 1,2,4-trimethoxybenzene, are brominated by NBS at room temperature.¹⁵ Both NCS and NBS can halogenate moderately active aromatics in nonpolar solvents by using HCl¹⁶ or HClO₄¹⁷ as a catalyst. Many other “positive halogen” compounds can act as halogenating agents. (See Table 4.2 for examples of such reagents.)

A wide variety of aromatic compounds can be brominated. Highly reactive ones, such as anilines and phenols, may undergo bromination at all activated positions. More selective reagents such as pyridinium bromide perbromide or tetraalkylammonium tribromides can be used in such cases.¹⁸ Moderately reactive compounds such as anilides, haloaromatics, and hydrocarbons can be readily brominated and the usual directing effects control the regiochemistry. Use of Lewis acid catalysts permits bromination of rings with deactivating substituents, such as nitro and cyano.

Halogenations are strongly catalyzed by mercuric acetate or trifluoroacetate. These conditions generate acyl hypohalites, which are the active halogenating agents. The trifluoroacetyl hypohalites are very reactive reagents. Even nitrobenzene, for example, is readily brominated by trifluoroacetyl hypobromite.¹⁹

A solution of bromine in CCl₄ containing sulfuric acid and mercuric oxide is also a reactive brominating agent.²⁰

Fluorination can be carried out using fluorine diluted with an inert gas. However, great care is necessary to avoid uncontrolled reaction.²¹ Several other reagents have been devised that are capable of aromatic fluorination.²² Acetyl hypofluorite can be prepared in situ from fluorine and sodium acetate.²³ This reagent effects fluorination

of activated aromatics. Although this procedure does not avoid the special precautions necessary for manipulation of elemental fluorine, it does provide a system with much greater selectivity. Acetyl hypofluorite shows a strong preference for *o*-fluorination of alkoxy and acetamido-substituted rings. *N*-Fluoro-*bis*-(trifluoromethanesulfonyl)amine (*N*-fluorotriflimide) displays similar reactivity and can fluorinate benzene and activated aromatics.²⁴

Several *N*-fluoro derivatives of 1,4-diazabicyclo[2.2.2]octane are useful for aromatic fluorination.²⁵

Iodinations can be carried out by mixtures of iodine and various oxidants such as periodic acid,²⁶ I_2O_5 ,²⁷ NO_2 ,²⁸ and $\text{Ce}(\text{NH}_3)_2(\text{NO}_3)_6$.²⁹ A mixture of a cuprous iodide and a cupric salt can also effect iodination.³⁰

Iodination of moderately reactive aromatics can be effected by mixtures of iodine and silver or mercuric salts.³¹ Hypoiodites are presumably the active iodinating species. *Bis*-(pyridine)iodonium salts can iodinate benzene and activated derivatives in the presence of strong acids such as HBF_4 or $\text{CF}_3\text{SO}_3\text{H}$.³²

Scheme 11.2 shows some representative halogenation reactions. Entries 1 and 2 involve Lewis acid-catalyzed chlorination. Entry 3 is an acid-catalyzed chlorination using NCS as the reagent. Entry 4 shows a high-yield chlorination of acetanilide by *t*-butyl hypochlorite. This seems to be an especially facile reaction, since anisole is not chlorinated under these conditions, and may involve the *N*-chloroamide as an intermediate. Entry 5 describes a large-scale chlorination done with NCS. The product was used for the synthesis of sulamserod, a drug candidate.

Entry 6 is a case of *meta* bromination of a deactivated aromatic. Entry 7 is a case in which all activated positions are brominated. It is interesting that the reaction occurs in acidic solution. It may be that each successive bromine addition accelerates the reaction by decreasing the basicity of the aniline and increasing the amount that is present in the neutral form. Entry 8 employs dibromoisocyanuric acid in concentrated H_2SO_4 as a brominating reagent. These conditions have been found useful for unreactive aromatics. Entry 9 is an example of bromination using NBS. Entry 10 uses bromine and mercuric oxide under conditions that were found effective for deactivated aromatics. Entry 11 describes conditions that are applicable for bromination of anilines. It is suggested that the reaction may involve formation of methyl hypobromite as the active bromination reagent.

Entries 12 to 18 show iodinations under various conditions. The reaction in Entry 12, using iodine monochloride, is done in concentrated HCl , but presumably occurs through the neutral form of the reactant ($\text{p}K_1 = 2.17$). Entries 13 and 14 involve reactions activated by mercuric and silver salts, respectively, and probably involve the

hypoiodites as the active reagents. Entry 15 uses iodine and periodic acid, a reagent combination that was found effective for moderately activated aromatics. The $\text{I}_2\text{-NO}_2$ combination illustrated in Entry 16 is also applicable to activated species. Entry 17 illustrates an oxidative procedure that can be used with moderately activated aromatics such as the methyl and methoxy derivatives of benzene. The *bis*-pyridine-iodonium reagent shown in Entry 18 was used with two equivalents of a strong acid, either HBF_4 or $\text{CF}_3\text{SO}_3\text{H}$, in dichloromethane. These conditions were applicable even to deactivated aromatics, such as methyl benzoate and nitrobenzene.

Entries 19 and 20 are fluorinations. In Entry 19, the fluorination is on an activated ring in the antinausea drug nabilone. Entry 20 illustrates the use *N,N'*-difluoro-1,4-diazabicyclo[2.2.2]octane ditriflate.

11.1.3. Friedel-Crafts Alkylation

Friedel-Crafts alkylation reactions are an important method for introducing carbon substituents on aromatic rings. The reactive electrophiles can be either discrete carbocations or polarized complexes that contain a reactive leaving group. Various combinations of reagents can be used to generate alkylating species. Alkylations usually involve alkyl halides and Lewis acids or reactions of alcohols or alkenes with strong acids.

Owing to the involvement of carbocations, Friedel-Crafts alkylations can be accompanied by rearrangement of the alkylating group. For example, isopropyl groups are often introduced when *n*-propyl reactants are used.³³

Similarly, under a variety of reaction conditions, alkylation of benzene with either 2-chloro or 3-chloropentane gives rise to a mixture of both 2-pentyl- and 3-pentylbenzene.³⁴

Rearrangement can also occur after the initial alkylation. The reaction of 2-chloro-2-methylbutane with benzene is an example of this behavior.³⁵ With relatively mild Friedel-Crafts catalysts such as BF_3 or FeCl_3 , the main product is **1**. With AlCl_3 , equilibration of **1** and **2** occurs and the equilibrium favors **2**. The rearrangement is the result of product equilibration via reversibly formed carbocations.

³³. S. H. Sharman, *J. Am. Chem. Soc.*, **84**, 2945 (1962).

³⁴. R. M. Roberts, S. E. McGuire, and J. R. Baker, *J. Org. Chem.*, **41**, 659 (1976).

³⁵. A. A. Khalaf and R. M. Roberts, *J. Org. Chem.*, **35**, 3717 (1970); R. M. Roberts and S. E. McGuire, *J. Org. Chem.*, **35**, 102 (1970).

Alkyl groups can also migrate from one position to another on the ring.³⁶ Such migrations are also thermodynamically controlled and proceed in the direction of minimizing steric interactions between substituents.

The relative reactivity of Friedel-Crafts catalysts has not been described in a quantitative way, but comparative studies using a series of benzyl halides has resulted in the qualitative groupings shown in Table 11.1. Proper choice of catalyst can minimize subsequent product equilibrations.

The Friedel-Crafts alkylation reaction does not proceed successfully with aromatic reactants having EWG substituents. Another limitation is that each alkyl group that is introduced *increases the reactivity of the ring toward further substitution*, so polyalkylation can be a problem. Polyalkylation can be minimized by using the aromatic reactant in excess.

Apart from the alkyl halide–Lewis acid combination, two other sources of carbocations are often used in Friedel-Crafts reactions. Alcohols can serve as carbocation precursors in strong acids such as sulfuric or phosphoric acid. Alkylation can also be effected by alcohols in combination with BF_3 or AlCl_3 .³⁷ Alkenes can serve as alkylating agents when a protic acid, especially H_2SO_4 , H_3PO_4 , and HF , or a Lewis acid, such as BF_3 and AlCl_3 , is used as a catalyst.³⁸

Stabilized carbocations can be generated from allylic and benzylic alcohols by reaction with $\text{Sc}(\text{O}_3\text{SCF}_3)_3$ and results in formation of alkylation products from benzene and activated derivatives.³⁹

This kind of reaction has been used to synthesize α -tocopherol, in a reaction that involves alkylation, followed by cyclization involving the phenyl hydroxy group.

Ref. 40

Methanesulfonate esters of secondary alcohols also give Friedel-Crafts products in the presence of $\text{Sc}(\text{O}_3\text{SCF}_3)_3$ ⁴¹ or $\text{Cu}(\text{O}_3\text{SCF}_3)_2$.⁴²

Friedel-Crafts alkylation can occur intramolecularly to form a fused ring. Intramolecular Friedel-Crafts reactions provide an important method for constructing polycyclic hydrocarbon frameworks. It is somewhat easier to form six-membered than five-membered rings in such reactions. Thus, whereas 4-phenyl-1-butanol gives a 50% yield of a cyclized product in phosphoric acid, 3-phenyl-1-propanol is mainly dehydrated to alkenes.⁴³

If a potential carbocation intermediate can undergo a hydride or alkyl shift, this shift occurs in preference to closure of the five-membered ring.

⁴⁴ A. A. Khalaf and R. M. Roberts, *J. Org. Chem.*, **37**, 4227 (1972).

These results reflect a rather general tendency for $6 > 5, 7$ in ring closure by intramolecular Friedel-Crafts reactions.^{44,45} The difficulty in forming five-membered rings may derive from steric and electronic factors. Some strain must develop because of the sp^2 carbons included in the ring. Perhaps more important is the need for approach perpendicular to the ring. With three of the five carbons coplanar, it is difficult to align the empty p orbital of the carbocation with the π system.

Scheme 11.3 gives some examples of both inter- and intramolecular Friedel-Crafts alkylations. Entry 1 is carried out using AlCl_3 in an excess of refluxing benzene. Entry 2 was also done using benzene as the solvent, but this reaction is done at 0°C . A tertiary carbocation is generated by protonation of the double bond. Entry 3 involves alkylation by both bromo substituents in the reactant. The reaction is carried out in excess benzene, using AlBr_3 . Entry 4 demonstrates the ability of a typical aromatic sulfonic acid to generate a reactive carbocation by alkene protonation. The reaction was carried out in excess toluene at 105°C . Note the relatively weak position selectivity (see also Part A, Section 9.4.4). Secondary alkyl tosylates are also sources of reactive carbocations under these conditions.

Entries 5 to 7 show intramolecular reactions. Entry 5 is an example of formation of a polycyclic ring system. The product is a 3:1 mixture of β : α methyl isomers at the new ring junction, and reflects a preference for TS **A** over TS **B**.

Entry 6 involves formation of a stabilized benzylic carbocation and results in a very efficient closure of a six-membered ring. Entry 7 involves an activated ring. The reaction was done using enantiomerically pure alcohol, but, as expected for a carbocation intermediate, the product was nearly racemic (6% e.e.). This cyclization was done enantiospecifically by first forming the $\text{Cr}(\text{CO})_3$ complex (see Section 8.5).

11.1.4. Friedel-Crafts Acylation

Friedel-Crafts acylation generally involves reaction of an acyl halide and Lewis acid such as AlCl_3 , SbF_5 , or BF_3 . Bismuth(III) triflate is also a very active acylation catalyst.⁴⁶ Acid anhydrides can also be used in some cases. For example, a combination

of hafnium(IV) triflate and LiClO_4 in nitromethane catalyzes acylation of moderately reactive aromatics by acetic anhydride.

Ref. 47

Mixed anhydrides with trifluoroacetic acid are particularly reactive acylating agents.⁴⁸ For example, Entry 5 in Scheme 11.4 shows the use of a mixed anhydride in the course of synthesis of the anticancer agent tamoxifen.

As in the alkylation reaction, the reactive intermediate in Friedel-Crafts acylation can be a dissociated acylium ion or a complex of the acid chloride and Lewis acyl.⁴⁹ Recent mechanistic studies have indicated that with benzene and slightly deactivated derivatives, it is the *protonated acylium ion* that is the kinetically dominant electrophile.⁵⁰

Regioselectivity in Friedel-Crafts acylations can be quite sensitive to the reaction solvent and other procedural variables.⁵¹ In general, *para* attack predominates for

alkylbenzenes.⁵² The percentage of *ortho* attack increases with the electrophilicity of the acylium ion and as much as 50% *ortho* product is observed with the formylium and 2,4-dinitrobenzoylium ions.⁵³ Rearrangement of the acyl group is not a problem in Friedel-Craft acylation. Neither is polyacylation, because the first acyl group serves to deactivate the ring to further attack. For these reasons, it is often preferable to introduce primary alkyl groups by a sequence of acylation followed by reduction of the acyl group (see Section 5.7.1).

Intramolecular acylations are very common, and the normal conditions involving an acyl halide and Lewis acid can be utilized. One useful alternative is to dissolve the carboxylic acid in polyphosphoric acid (PPA) and heat to effect cyclization. This procedure probably involves formation of a mixed phosphoric-carboxylic anhydride.⁵⁴

Cyclizations can also be carried out with an esterified oligomer of phosphoric acid called “polyphosphate ester,” which is chloroform soluble.⁵⁵ Another reagent of this type is trimethylsilyl polyphosphate (Scheme 11.4, Entry 13).⁵⁶ Neat methanesulfonic acid is also an effective reagent for intramolecular Friedel-Crafts acylation (Scheme 11.4, Entry 14).⁵⁷

A classical procedure for fusing a six-membered ring to an aromatic ring uses succinic anhydride or a derivative. An intermolecular acylation is followed by reduction and an intramolecular acylation. The reduction step is necessary to provide a more reactive ring for the second acylation.

Ref. 58

Scheme 11.4 shows some other representative Friedel-Crafts acylation reactions. Entries 1 and 2 show typical Friedel-Crafts acylation reactions using AlCl_3 . Entries 3 and 4 are similar, but include some functionality in the acylating reagents. Entry 5 involves formation of a mixed trifluoroacetic anhydride, followed by acylation in 85% H_3PO_4 . The reaction was conducted on a kilogram scale and provides a starting material for the synthesis of tamoxifen. Entry 6 illustrates the use of bismuth triflate as

a Lewis acid. Entries 7 and 8 exemplify typical conditions for intramolecular Friedel-Crafts reactions. In Entry 9, both alkylation and acylation occur, presumably in that order.

In Entry 10, intramolecular acylation is followed by dehydrohalogenation. Entries 11 and 12 illustrate the use of polyphosphate ester. The cyclization in Entry 13 is done in neat methanesulfonic acid.

A special case of aromatic acylation is the *Fries rearrangement*, which is the conversion of an ester of a phenol to an *o*-acyl phenol by a Lewis acid.

Lanthanide triflates are also good catalysts for Fries rearrangements.⁶¹

11.1.5. Related Alkylation and Acylation Reactions

There are a number of variations of the Friedel-Crafts reactions that are useful in synthesis. The introduction of chloromethyl substituents is brought about by reaction with formaldehyde in concentrated hydrochloric acid and halide salts, especially zinc chloride.⁶² The reaction proceeds with benzene and activated derivatives. The reactive electrophile is probably the chloromethyl cation.

Chloromethylation can also be carried out using various chloromethyl ethers and SnCl_4 .⁶³

Carbon monoxide, hydrogen cyanide, and nitriles also react with aromatic compounds in the presence of strong acids or Friedel-Crafts catalysts to introduce formyl or acyl substituents. The active electrophiles are believed to be *dications* resulting from diprotonation of CO, HCN, or the nitrile.⁶⁴ The general outlines of the mechanisms of these reactions are given below.

a. Formylation with carbon monoxide:

b. Formylation with hydrogen cyanide:

c. Acylation with nitriles:

Many specific examples of these reactions can be found in reviews in the *Organic Reactions* series.⁶⁵ Dichloromethyl ethers are also precursors of the formyl group via alkylation catalyzed by SnCl_4 or TiCl_4 .⁶⁶ The dichloromethyl group is hydrolyzed to a formyl group.

Another useful method for introducing formyl and acyl groups is the *Vilsmeier-Haack reaction*.⁶⁷ *N,N*-dialkylamides react with phosphorus oxychloride or oxalyl chloride⁶⁸ to give a chloroiminium ion, which is the reactive electrophile.

This species acts as an electrophile in the absence of any added Lewis acid, but only rings with ERG substituents are reactive.

Scheme 11.5 gives some examples of these acylation reactions. Entry 1 is an example of a chloromethylation reaction. Entry 2 is a formylation using carbon monoxide. Entry 3 is an example of formylation via *bis*-chloromethyl ether. A cautionary note on this procedure is the potent carcinogenicity of this reagent. Entries 4 and 5 are examples of formylation and acetylation, using HCN and acetonitrile, respectively. Entries 6 to 8 are examples of Vilsmeier-Haack reactions, all of which are conducted on strongly activated aromatics.

11.1.6. Electrophilic Metallation

Aromatic compounds react with mercuric salts to give arylmercury compounds.⁶⁹ Mercuric acetate or mercuric trifluoroacetate are the usual reagents.⁷⁰ The reaction shows substituent effects that are characteristic of electrophilic aromatic substitution.⁷¹ Mercuration is one of the few electrophilic aromatic substitutions in which proton loss from the σ complex is rate determining. Mercuration of benzene shows an isotope effect $k_{\text{H}}/k_{\text{D}} = 6$,⁷² which indicates that the σ complex must be formed reversibly.

The synthetic utility of the mercuration reaction derives from subsequent transformations of the arylmercury compounds. As indicated in Section 7.3.3, these compounds are only weakly nucleophilic, but the carbon-mercury bond is reactive to various electrophiles. They are particularly useful for synthesis of nitroso compounds. The nitroso group can be introduced by reaction with nitrosyl chloride⁷³ or nitrosonium tetrafluoroborate⁷⁴ as the electrophile. Arylmercury compounds are also useful in certain palladium-catalyzed reactions, as discussed in Section 8.2.

Thallium(III), particularly as the trifluoroacetate salt, is also a reactive electrophilic metallating species, and a variety of synthetic schemes based on arylthallium intermediates have been devised.⁷⁵ Arylthallium compounds are converted to chlorides or bromides by reaction with the appropriate cupric halide.⁷⁶ Reaction with potassium iodide gives aryl iodides.⁷⁷ Fluorides are prepared by successive treatment with potassium fluoride and boron trifluoride.⁷⁸ Procedures for converting arylthallium compounds to nitriles and phenols have also been described.⁷⁹

The thallium intermediates can be useful in directing substitution to specific positions when the site of thallation can be controlled in an advantageous way. The two principal means of control are chelation and the ability to effect thermal equilibration of arylthallium intermediates. Oxygen-containing groups normally direct thallation to the *ortho* position by a chelation effect. The thermodynamically favored position is

normally the *meta* position, and heating the thallium derivatives of alkylbenzenes gives a predominance of the *meta* isomer.⁸⁰ Both mercury and thallium compounds are very toxic, so special care is needed in their manipulation.

11.2. Nucleophilic Aromatic Substitution

Synthetically important substitutions of aromatic compounds can also be done by nucleophilic reagents. There are several general mechanism for substitution by nucleophiles. Unlike nucleophilic substitution at saturated carbon, aromatic nucleophilic substitution does not occur by a single-step mechanism. The broad mechanistic classes that can be recognized include addition-elimination, elimination-addition, and metal-catalyzed processes. (See Section 9.5 of Part A to review these mechanisms.) We first discuss diazonium ions, which can react by several mechanisms. Depending on the substitution pattern, aryl halides can react by either addition-elimination or elimination-addition. Aryl halides and sulfonates also react with nucleophiles by metal-catalyzed mechanisms and these are discussed in Section 11.3.

11.2.1. Aryl Diazonium Ions as Synthetic Intermediates

The first widely used intermediates for nucleophilic aromatic substitution were the aryl diazonium salts. Aryl diazonium ions are usually prepared by reaction of an aniline with nitrous acid, which is generated in situ from a nitrite salt.⁸¹ Unlike aliphatic diazonium ions, which decompose very rapidly to molecular nitrogen and a carbocation (see Part A, Section 4.1.5), aryl diazonium ions are stable enough to exist in solution at room temperature and below. They can also be isolated as salts with nonnucleophilic anions, such as tetrafluoroborate or trifluoroacetate.⁸² Salts prepared with *o*-benzenedisulfonimide also appear to have potential for synthetic application.⁸³

benzenedisulfonimide anion

The steps in forming a diazonium ion are addition of the nitrosonium ion, ^+NO , to the amino group, followed by elimination of water.

In alkaline solution, diazonium ions are converted to diazoate anions, which are in equilibrium with diazo oxides.⁸⁴

In addition to the aqueous method for diazotization in aqueous solution, diazonium ions can be generated in organic solvents by reaction with alkyl nitrites.

Diazonium ions form stable adducts with certain nucleophiles such as secondary amines and sulfide anions.⁸⁵ These compounds can be used as precursors of diazonium ion intermediates.

The wide utility of aryl diazonium ions as synthetic intermediates results from the excellence of N_2 as a leaving group. There are several general mechanisms by which substitution can occur. One involves unimolecular thermal decomposition of the diazonium ion, followed by capture of the resulting aryl cation by a nucleophile. The phenyl cation is very unstable (see Part A, Section 3.4.1.1) and therefore highly unselective.⁸⁶ Either the solvent or an anion can act as the nucleophile.

Another general mechanism for substitution is adduct formation followed by collapse of the adduct with loss of nitrogen.

⁸⁴ E. S. Lewis and M. P. Hanson, *J. Am. Chem. Soc.*, **89**, 6268 (1967).

⁸⁶ C. G. Swain, J. E. Sheats, and K. G. Harbison, *J. Am. Chem. Soc.*, **97**, 783 (1975).

A third mechanism involves redox processes,⁸⁷ and is particularly likely to operate in reactions in which copper salts are used as catalysts.⁸⁸

Examples of the three mechanistic types are, respectively: (a) hydrolysis of diazonium salts to phenols⁸⁹; (b) reaction with azide ion to form aryl azides⁹⁰; and (c) reaction with cuprous halides to form aryl chlorides or bromides.⁹¹ In the paragraphs that follow, these and other synthetically useful reactions of diazonium intermediates are considered. The reactions are organized on the basis of the group that is introduced, rather than on the mechanism involved. It will be seen that the reactions that are discussed fall into one of the three general mechanistic types.

11.2.1.1. Reductive Dediazonization. Replacement of a nitro or amino group by hydrogen is sometimes required as a sequel to a synthetic operation in which the substituent was used to control the position selectivity of a prior transformation. The best reagents for reductive dediazonation are hypophosphorous acid, H_3PO_2 ,⁹² and NaBH_4 .⁹³ The reduction by H_3PO_2 is substantially improved by catalysis with cuprous oxide.⁹⁴ The reduction by H_3PO_2 proceeds by one-electron reduction followed by loss of nitrogen and formation of the phenyl radical.⁹⁵ The hypophosphorous acid then serves as a hydrogen atom donor.

An alternative method for reductive dediazonation involves in situ diazotization by an alkyl nitrite in dimethylformamide.⁹⁶ This reduction is a chain reaction with the solvent acting as the hydrogen atom donor.

This reaction can be catalyzed by FeSO_4 .⁹⁷

11.2.1.2. Phenols from Diazonium Ion Intermediates. Aryl diazonium ions can be converted to phenols by heating in water. Under these conditions, there is probably formation of a phenyl cation.

By-products from capture of nucleophilic anions may be observed.⁵³ Phenols can be formed under milder conditions by an alternative redox mechanism.⁹⁸ The reaction is initiated by cuprous oxide, which effects reduction and decomposition to an aryl radical, and is run in the presence of Cu(II) salts. The radical is captured by Cu(II) and converted to the phenol by reductive elimination. This procedure is very rapid and gives good yields of phenols over a range of structural types.

11.2.1.3. Aryl Halides from Diazonium Ion Intermediates. Replacement of diazonium groups by halides is a valuable alternative to direct halogenation for the preparation of aryl halides. Aryl bromides and chlorides are usually prepared by a reaction using the appropriate Cu(I) salt, which is known as the *Sandmeyer reaction*. Under the classic conditions, the diazonium salt is added to a hot acidic solution of the cuprous halide.⁹⁹ The Sandmeyer reaction occurs by an oxidative addition reaction of the diazonium ion with Cu(I) and halide transfer from a Cu(III) intermediate.

Good yields of chlorides have also been obtained for reaction of isolated diazonium tetrafluoroborates with FeCl_2 - FeCl_3 mixtures.¹⁰⁰ It is also possible to convert anilines to aryl halides by generating the diazonium ion in situ. Reaction of anilines with alkyl nitrites and Cu(II) halides in acetonitrile gives good yields of aryl chlorides and bromides.¹⁰¹

Diazonium salts can also be converted to halides by processes involving aryl free radicals. In basic solutions, aryl diazonium ions are converted to radicals via the diazo oxide.¹⁰²

The reaction can be carried out efficiently using aryl diazonium tetrafluoroborates with crown ethers, polyethers, or phase transfer catalysts.¹⁰³ In solvents that can act as halogen atom donors, the radicals react to give aryl halides. Bromotrichloromethane gives aryl bromides, whereas methyl iodide and diiodomethane give iodides.¹⁰⁴ The diazonium ions can also be generated by in situ methods. Under these conditions bromoform and bromotrichloromethane have been used as bromine donors and carbon tetrachloride is the best chlorine donor.¹⁰⁵ This method was used successfully for a challenging chlorodeamination in the vancomycin system.

Fluorine substituents can also be introduced via diazonium ions. One procedure is to isolate aryl diazonium tetrafluoroborates. These decompose thermally to give aryl fluorides.¹⁰⁶ Called the *Schiemann reaction*, it probably involves formation of an aryl cation that abstracts fluoride ion from the tetrafluoroborate anion.¹⁰⁷

Hexfluorophosphate salts behave similarly.¹⁰⁸ The diazonium tetrafluoroborates can be prepared either by precipitation from an aqueous solution by fluoroboric acid¹⁰⁹ or by anhydrous diazotization in ether, THF, or acetonitrile using *t*-butyl nitrite and boron trifluoride.¹¹⁰ Somewhat milder reaction conditions can be achieved by reaction of aryl diazo sulfide adducts with pyridine-HF in the presence of AgF or AgNO₃.

Aryl diazonium ions are converted to iodides in high yield by reaction with iodide salts. This reaction is initiated by reduction of the diazonium ion by iodide. The aryl radical then abstracts iodine from either I₂ or I₃⁻. A chain mechanism then proceeds

and consumes I^- and ArN_2^+ .¹¹² Evidence for the involvement of radicals includes the isolation of cyclized products from *o*-allyl derivatives.

11.2.1.4. Introduction of Other Nucleophiles Using Diazonium Ion Intermediates. Cyano and azido groups are also readily introduced via diazonium intermediates. The former involves a copper-catalyzed reaction analogous to the Sandmeyer reaction. Reaction of diazonium salts with azide ion gives adducts that smoothly decompose to nitrogen and the aryl azide.⁵⁶

Aryl thiolates react with aryl diazonium ions to give diaryl sulfides. This reaction is believed to be a radical chain process, similar to the mechanism for reaction of diazonium ions with iodide ion.¹¹³

Scheme 11.6 gives some examples of the various substitution reactions of aryl diazonium ions. Entries 1 to 6 are examples of reductive dediazonization. Entry 1 is an older procedure that uses hydrogen abstraction from ethanol for reduction. Entry 2 involves reduction by hypophosphorous acid. Entry 3 illustrates use of copper catalysis in conjunction with hypophosphorous acid. Entries 4 and 5 are DMF-mediated reductions, with ferrous catalysis in the latter case. Entry 6 involves reduction by NaBH_4 .

Entries 7 and 8 illustrate conversion of diazonium salts to phenols. Entries 9 and 10 use the traditional conditions for the Sandmeyer reaction. Entry 11 is a Sandmeyer reaction under in situ diazotization conditions, whereas Entry 12 involves halogen atom transfer from solvent. Entry 13 is an example of formation of an aryl iodide. Entries 14 and 15 are Schiemann reactions. The reaction in Entry 16 was used to introduce a chlorine substituent on vancomycin. Of several procedures investigated, the $\text{CuCl}-\text{CuCl}_2$ catalysis of chlorine atom transfer from CCl_4 proved to be the best. The diazonium salt was isolated as the tetrafluoroborate after in situ diazotization. Entries 17 and 18 show procedures for introducing cyano and azido groups, respectively.

11.2.1.5. Meerwein Arylation Reactions. Aryl diazonium ions can also be used to form certain types of carbon-carbon bonds. The copper-catalyzed reaction of diazonium ions with conjugated alkenes results in arylation of the alkene, known as the *Meerwein arylation reaction*.¹¹⁴ The reaction sequence is initiated by reduction of the diazonium ion by Cu(I). The aryl radical adds to the alkene to give a new β -aryl radical. The final step is a ligand transfer that takes place in the copper coordination sphere. An alternative course is oxidation-deprotonation, which gives a styrene derivative.

The reaction gives better yield with dienes, styrenes, or alkenes substituted with EWGs than with simple alkenes. These groups increase the rate of capture of the aryl radical. The standard conditions for the Meerwein arylation employ aqueous solutions of diazonium ions. Conditions for in situ diazotization by *t*-butyl nitrite in the presence of CuCl₂ and acrylonitrile or styrene are also effective.¹¹⁵

Reduction of aryl diazonium ions by Ti(III) in the presence of α,β -unsaturated ketones and aldehydes leads to β -arylation and formation of the saturated ketone or aldehyde. The early steps in this reaction parallel the copper-catalyzed reaction. However, rather than being oxidized, the radical formed by the addition step is reduced by Ti(III).¹¹⁶

Scheme 11.7 illustrates some arylation of alkenes by diazonium ions. Entries 1 to 4 are typical conditions. Entry 5 illustrates generation of the diazonium ion under in situ conditions. Entry 6 is an example of the reductive conditions using Ti(III).

11.2.2. Substitution by the Addition-Elimination Mechanism

The addition of a nucleophile to an aromatic ring, followed by elimination of a substituent, results in nucleophilic substitution. The major energetic requirement for this mechanism is formation of the addition intermediate. The addition step is greatly facilitated by strongly electron-attracting substituents, and nitroaromatics are the best reactants for nucleophilic aromatic substitution. Other EWGs such as cyano, acetyl, and trifluoromethyl also enhance reactivity.

Nucleophilic substitution occurs when there is a potential leaving group present at the carbon at which addition occurs. Although halides are the most common leaving groups, alkoxy, cyano, nitro, and sulfonyl groups can also be displaced. The leaving group ability does not necessarily parallel that found for nucleophilic substitution at saturated carbon. As a particularly striking example, fluoride is often a better leaving group than the other halogens in nucleophilic aromatic substitution. The relative reactivity of the *p*-halonitrobenzenes toward sodium methoxide at 50°C is F(312) >> Cl(1) > Br (0.74) > I (0.36).¹¹⁷ A principal reason for the order I > Br > Cl > F in S_N2 reactions is the carbon-halogen bond strength, which increases from I to F. The carbon-halogen bond strength is not so important a factor in nucleophilic aromatic substitution because bond breaking is not ordinarily part of the rate-determining step. Furthermore, the highly electronegative fluorine favors the addition step more than the other halogens.

The addition-elimination mechanism has been used primarily for arylation of oxygen and nitrogen nucleophiles. There are not many successful examples of arylation of carbanions by this mechanism. A major limitation is the fact that aromatic nitro

¹¹⁷ G. P. Briner, J. Mille, M. Liveris, and P. G. Lutz, *J. Chem. Soc.*, 1265 (1954).

compounds often react with carbanions by electron transfer processes.¹¹⁸ However, substitution by carbanions can be carried out under the conditions of the $S_{RN}1$ reaction (see Section 11.4).

The pyridine family of heteroaromatic nitrogen compounds is reactive toward nucleophilic substitution at the C(2) and C(4) positions. The nitrogen atom serves to activate the ring toward nucleophilic attack by stabilizing the addition intermediate. This kind of substitution reaction is especially important in the chemistry of pyrimidines.

Ref. 119

Ref. 120

A variation of the aromatic nucleophilic substitution process in which the leaving group is part of the entering nucleophile has been developed and is known as *vicarious nucleophilic aromatic substitution*. These reactions require a strong EWG substituent such as a nitro group but require no halide or other leaving group. The reactions proceed through addition intermediates.¹²¹

The combinations $Z = \text{CN}$, RSO_2 , CO_2R , and SR and $X = \text{F}$, Cl , Br , I , ArO , ArS , and $(\text{CH}_3)_2\text{NCS}_2$ are among those that have been demonstrated.¹²²

Scheme 11.8 gives some examples of addition-elimination reactions. Entries 1 and 2 illustrate typical *o*- and *p*-nitrophenylations of amines. Note the rather vigorous conditions that are required. Entry 3 shows a rather unusual case in which an acetyl group is the activating substituent. Good yields were obtained for a number of amines in polar aprotic solvents. The corresponding chloro and bromo derivative were much less reactive. Entry 4 represents a case of a very electrophilic aromatic ring, but

the favored addition intermediate does not have a potential leaving group. Reaction evidently occurs through a minor adduct.

Entry 5 involves metallic copper as a catalyst and is probably a metal-catalyzed reaction (see Section 11.3). The reaction is carried out with excess phenol without solvent. Entries 6 and 7 are cases of C-arylation, both using 2,4-dinitrochlorobenzene.

11.2.3. Substitution by the Elimination-Addition Mechanism

The elimination-addition mechanism involves a highly unstable intermediate called *dehydrobenzene* or *benzyne*.¹²³ (See Section 10.6 of Part A for a discussion of the structure of benzyne.)

A unique feature of this mechanism is that the entering nucleophile does not necessarily become bound to the carbon to which the leaving group was attached.

The elimination-addition mechanism is facilitated by electronic effects that favor removal of a hydrogen from the ring as a proton. Relative reactivity also depends on the halide. The order $\text{Br} > \text{I} > \text{Cl} > \text{F}$ has been established in the reaction of aryl halides with KNH_2 in liquid ammonia¹²⁴ and has been interpreted as representing a balance of two effects. The polar order favoring proton removal would be $\text{F} > \text{Cl} > \text{Br} > \text{I}$, but this is largely overwhelmed by the ease of bond breaking, which is $\text{I} > \text{Br} > \text{Cl} > \text{F}$. With organolithium reagents in ether solvents, the order of reactivity is $\text{F} > \text{Cl} > \text{Br} > \text{I}$, which indicates that the acidity of the ring hydrogen is the dominant factor governing reactivity.¹²⁵

Benzyne can also be generated from *o*-dihaloaromatics. Reaction with lithium amalgam or magnesium results in the formation of transient organometallic compounds that decompose with elimination of lithium halide. *o*-Fluorobromobenzene is the usual starting material in this procedure.¹²⁶

There are several methods for generation of benzyne in addition to base-catalyzed elimination of hydrogen halide from a halobenzene and some of these are more generally applicable for preparative work. Probably the most useful method is diazotization of *o*-aminobenzoic acids.¹²⁷ Loss of nitrogen and carbon dioxide follows diazotization and generates benzyne. This method permits generation of benzyne in the presence of a number of molecules with which it can react.

Oxidation of 1-aminobenzotriazole also serves as a source of benzyne under mild conditions. An oxidized intermediate decomposes with loss of two molecules of nitrogen.¹²⁸

Another heterocyclic molecule that can serve as a benzyne precursor is benzothiadiazole-1,1-dioxide, which decomposes with elimination of nitrogen and sulfur dioxide.¹²⁹

Addition of nucleophiles such as ammonia or alcohols, or their conjugate bases, to benzyne takes place very rapidly. The addition is believed to involve capture of the nucleophile by benzyne, followed by protonation to give the substitution product.¹³⁰ Electronegative groups tend to favor addition of the nucleophile at the more distant end of the “triple bond,” since this permits stabilization of the developing negative charge. Selectivity is usually not high, however, and formation of both possible products from monosubstituted benzyne is common.¹³¹

When benzyne is generated in the absence of another reactive molecule it dimerizes to biphenylene.¹³² In the presence of dienes, benzyne is a very reactive dienophile and [4+2] cycloaddition products are formed. The adducts with furans can be converted to polycyclic aromatic compounds by elimination of water. Similarly, cyclopentadienones can give a new aromatic ring by loss of carbon monoxide. Pyrones give adducts that can aromatize by loss of CO₂, as illustrated by Entry 7 in Scheme 11.9.

Benzyne gives both [2+2] cycloaddition and ene reaction products with simple alkenes.¹³⁶

Scheme 11.9 illustrates some of the types of compounds that can be prepared via benzyne intermediates. Entry 1 is an example of the generation of benzyne in a strongly basic DMSO solution. Entry 2 is a Diels-Alder reaction involving in situ generation of benzyne. The adduct was used to synthesize several polycyclic strained-ring systems having fused benzene rings. Entry 3 illustrates the formation of benzyne from *o*-bromofluorobenzene by reaction with magnesium. The benzyne undergoes a Diels-Alder reaction with anthracene. Entry 4 also uses this method of benzyne generation and results in a [2+2] cycloaddition with an enamine. Entry 5 is photolytic generation of benzyne employing phthaloyl peroxide. This method seems to have been used only rarely. Entry 6 shows a case of intramolecular trapping of benzyne by a nitrile-stabilized carbanion. Entry 7 is a Diels-Alder reaction with a pyrone, in which the adduct undergoes decarboxylation under the reaction conditions.

11.3. Transition Metal–Catalyzed Aromatic Substitution Reactions

11.3.1. Copper-Catalyzed Reactions

As noted in Section 11.2.2, nucleophilic substitution of aromatic halides lacking activating substituents is generally difficult. It has been known for a long time that the nucleophilic substitution of aromatic halides can be catalyzed by the presence of copper metal or copper salts.¹³⁷ Synthetic procedures based on this observation are used to prepare aryl nitriles by reaction of aryl bromides with Cu(I)CN. The reactions are usually carried out at elevated temperature in DMF or a similar solvent.

¹³⁷ J. Lindley, *Tetrahedron*, **40**, 1433 (1984).

Ref. 138

Ref. 139

A general mechanistic description of the copper-promoted nucleophilic substitution involves an oxidative addition of the aryl halide to Cu(I) followed by collapse of the arylcopper intermediate with a ligand transfer (reductive elimination).¹⁴⁰

Several other kinds of nucleophiles can be arylated by copper-catalyzed substitution. Among the reactive nucleophiles are carboxylate ions,¹⁴¹ alkoxide ions,¹⁴² amines,¹⁴³ phthalimide anions,¹⁴⁴ thiolate anions,¹⁴⁵ and acetylides.¹⁴⁶ In some of these reactions there is competitive reduction of the aryl halide to the dehalogenated arene, which is attributed to protonolysis of the arylcopper intermediate. Most of these reactions are carried out at high temperature under heterogeneous conditions using copper powder or copper bronze as the catalyst. The general mechanism suggests that these catalysts act as sources of Cu(I) ions. Homogeneous reactions can be carried out using soluble Cu(I) salts, particularly Cu(I)O₃SCF₃.¹⁴⁷ These reactions occur under milder conditions than those using other sources of copper. The range and effectiveness of coupling aryl halides and phenolates to give diaryl ethers is improved by use of with CsCO₃.¹⁴⁸ Reaction occurs in refluxing toluene.

Some reactions of this type are accelerated further by use of naphthoic acid as an additive. This effect is believed to result from formation of a mixed anionic cuprate

having naphthoate as one of the ligands. The Cs^+ salts are beneficial in maximizing the solubility of the phenolate and naphthoates.

It has been found that a number of bidentate ligands greatly expand the scope of copper catalysis. Copper(I) iodide used in conjunction with a chelating diamine is a good catalyst for amidation of aryl bromides. Of several diamines that were examined, *trans*-*N,N'*-dimethylcyclohexane-1,2-diamine was among the best. These conditions are applicable to aryl bromides and iodides with either ERG or EWG substituents, as well as to relatively hindered halides. The nucleophiles that are reactive under these conditions include acyclic and cyclic amides.¹⁴⁹

This catalytic system also promotes exchange of iodide for bromide on aromatic rings.¹⁵⁰ The reaction is an equilibrium process that is driven forward by the low solubility of NaBr in the solvent, dioxane.

The *N,N*-diethylamide of salicylic acid is a useful ligand in conjunction with CuI and permits amination of aryl bromides by primary alkylamines.¹⁵¹

Copper(I) iodide with 1,10-phenanthroline catalyzes substitution of aryl iodides by alcohols. The reaction can be done either in excess alcohol or in toluene.¹⁵²

These copper-catalyzed reactions are generally applicable to aryl halides with either EWG or ERG substituents. The order of reactivity is $\text{I} > \text{Br} > \text{Cl} > \text{OSO}_2\text{R}$, which is consistent with an oxidative addition mechanism.

One aspect of the copper catalytic system that has received attention is the identity of the active catalytic species. In the case of displacement of aryl bromides by methoxide ion in the presence of CuBr, it has been suggested that the active species is Cu(I)(OCH₃)₂, an anionic cuprate.¹⁵³

11.3.2. Palladium-Catalyzed Reactions

In Section 8.2.3.2, we discussed arylation of enolates and enolate equivalents using palladium catalysts. Related palladium-phosphine combinations are very effective catalysts for aromatic nucleophilic substitution reactions. For example, conversion of aryl iodides to nitriles can be done under mild conditions with Pd(PPh₃)₄ as a catalyst.

Ref. 154

A great deal of effort has been devoted to finding efficient catalysts for substitution by oxygen and nitrogen nucleophiles.¹⁵⁵ These studies have led to optimization of the catalysis with ligands such as triarylphosphines,¹⁵⁶ *bis*-phosphines such as BINAP,¹⁵⁷ dppf,¹⁵⁸ and phosphines with additional chelating substituents.¹⁵⁹ Among the most effective catalysts are highly hindered trialkyl phosphines such as tri-*t*-butyl and tricyclohexylphosphine.¹⁶⁰ A series of 2-biphenylphosphines **3–6** has also been found to have excellent activity.¹⁶¹

A stable palladacycle **7** derived from biphenyl is also an active catalyst.¹⁶²

In addition to bromides and iodides, the reaction has been successfully extended to chlorides,¹⁶³ triflates,¹⁶⁴ and nonafluorobutanesulfonates (nonaflates).¹⁶⁵ These reaction conditions permit substitution in both electron-poor and electron-rich aryl systems by a variety of nitrogen nucleophiles, including alkyl or aryl amines and heterocycles. These reactions proceed via a catalytic cycle involving Pd(0) and Pd(II) intermediates.

Some of the details of the mechanism may differ for various catalytic systems. There have been kinetic studies on two of the amination systems discussed here. The results of a study of the kinetics of amination of bromobenzene using $\text{Pd}_2(\text{dba})_3$, BINAP, and sodium *t*-amyloxide in toluene were consistent with the oxidative addition occurring *after* addition of the amine at Pd. The reductive elimination is associated with *deprotonation of the aminated palladium complex*.¹⁶⁶

¹⁶⁶ U. K. Singh, E. R. Strieter, D. G. Blackmond, and S. L. Buchwald, *J. Am. Chem. Soc.*, **124**, 14104 (2002).

A study of the reaction of chlorobenzene with *N*-methylaniline in the presence of $\text{Pd}[\text{P}(t\text{-Bu})_3]_2$ and several different bases indicated that two mechanisms may occur concurrently, with their relative importance depending on the base, as indicated in the catalytic cycle below. The cycle on the right depicts oxidative addition followed by ligation by the deprotonated amine. The cycle on the left suggests that oxidative addition occurs on an anionic adduct of the catalyst and the base, followed by exchange with the amine ligand.¹⁶⁷

A comparison of several of the biphenylphosphine ligands has provided some insight into the mechanism of catalyst activation.¹⁶⁸ The results of this study suggest that dissociation of the diphosphino to a monophosphino complex is an essential step in catalyst activation, which would explain why some of the most hindered phosphines are among the best catalyst ligands. This study also indicated that deprotonation of the amine ligand is an essential step. Finally, in catalyst systems that are based on Pd(II) salts, there must be a mechanism for reduction to the active Pd(0) species. In the case of amines, this may occur by reduction by the amine ligand.

Steps in Catalyst Activation

The various palladium species can be subject to decomposition and deposition of palladium metal, which generally leads to catalyst inactivation. Apart from their effect on the catalyst activity, the ligands and bases also affect catalyst longevity.

Most of the synthetic applications to date have been based on empirical screening and comparison of ligand systems for effectiveness. A number of useful procedures have been developed. Aryl chlorides are generally less reactive than iodides and

¹⁶⁸. E. R. Strieter, D. G. Blackmond, and S. L. Buchwald, *J. Am. Chem. Soc.*, **125**, 13978 (2003).

bromides. The palladacycle **7** (see p. 1046), was used successfully in the amination of aryl chlorides.¹⁶⁹

Palladium-catalyzed substitution can also be applied to nonbasic nitrogen heterocycles, such as indoles, in the absence of strong bases.

Ref. 170

Except for the perfluoro cases, aryl sulfonates are generally less reactive than the halides. However certain catalyst systems can achieve reactions with benzenesulfonates and tosylates. The hindered biphenylphosphines are the most effective ligands.

Ref. 171

These conditions were also successfully applied to arylation of amides and carbamates.

Amination of tosylates has been achieved using a hindered ferrocenyldiphosphine ligand.¹⁷²

Similar reactions have been used for substitution by alkoxide and phenoxide nucleophiles. Hindered binaphthyl ligands have proven useful in substitutions by alcohols.¹⁷³

Palladium acetate in conjunction with a diphosphine ligand, xantphos, is active for arylation of amides, ureas, oxazolidinones and sulfonamides.¹⁷⁴

Some other examples of metal-catalyzed substitutions are given in Scheme 11.10. Entries 1 to 3 are copper-catalyzed reactions. Entry 1 is an example of arylation of imidazole. Both dibenzylideneacetone and 1,10-phenanthroline were included as ligands and Cs_2CO_3 was used as the base. Entry 2 is an example of amination by a primary amine. The ligand used in this case was *N,N*-diethylsalicylamide. These conditions proved effective for a variety of primary amines and aryl bromides with both ERG and EWG substituents. Entry 3 is an example of more classical conditions. The target structure is a phosphodiesterase inhibitor of a type used in treatment of asthma. Copper powder was used as the catalyst.

The remainder of the entries in Scheme 11.10 depict palladium-catalyzed reactions. Entries 4 to 6 are examples of aminations of aryl chlorides. In Entry 4, a Pd(II) salt with a hindered phosphine ligand was used as the catalyst. Entry 5 uses the Pd(0)-tri-(*t*-butyl)phosphine complex as the catalyst in conjunction with a phase transfer salt. The reaction was done in a water-toluene mixture and these conditions were applicable to chlorides with both ERG and EWG substituents. Entry 6 used the biphenyl ligand **4** (see p. 1046). LiHMDS was a particularly good base in this case. Entries 7 to 11 use bromides (or iodides) as reactants and *t*-alkoxides as bases. In cases where the catalyst source is a Pd(II) salt, catalyst activation by reduction is necessary. Entry 12 is a large-scale amination carried out using the imine of benzophenone as the nucleophile, with subsequent hydrolysis to provide the amine. Entries 13 and 14 use aryl triflates as reactants. Again, the palladium sources must be reduced as part of catalyst activation. Entry 15 is an example of arylation of an amide. The conditions are similar to those for amination, and subsequent studies have shown that many other nonbasic nitrogen compounds can be arylated (e.g. see p. 1049). Entries 16 to 19 involve alkoxide and phenoxide nucleophiles. The best ligands for these reactions seem to be highly hindered phosphines.

11.4. Aromatic Substitution Reactions Involving Radical Intermediates

11.4.1. Aromatic Radical Substitution

Aromatic rings are moderately reactive toward addition of free radicals (see Part A, Section 12.2) and certain synthetically useful substitution reactions involve free radical substitution. One example is the synthesis of biaryls.¹⁷⁵

There are some inherent limits to the usefulness of such reactions. Radical substitutions are only moderately sensitive to substituent directing effects, so that substituted reactants usually give a mixture of products. This means that the practical utility is limited to symmetrical reactants, such as benzene, where the position of attack

¹⁷⁵ W. E. Bachmann and R. A. Hoffman, *Org. React.*, **2**, 224 (1944); D. H. Hey, *Adv. Free Radical Chem.*, **2**, 47 (1966).

is immaterial. The best sources of aryl radicals are aryl diazonium ions and *N*-nitrosoacetanilides. In the presence of base, diazonium ions form diazooxides, which decompose to aryl radicals.¹⁷⁶

In the classical procedure, base is added to a two-phase mixture of the aqueous diazonium salt and an excess of the aromatic that is to be substituted. Improved yields can be obtained by using polyethers or phase transfer catalysts with solid aryl diazonium tetrafluoroborate salts in an excess of the aromatic reactant.¹⁷⁷ Another source of aryl radicals is *N*-nitrosoacetanilides, which rearrange to diazonium acetates and give rise to aryl radicals via diazo oxides.¹⁷⁸

A procedure for arylation involving in situ diazotization has also been developed.¹⁷⁹

Scheme 11.11 gives some representative preparative reactions based on these methods. Entry 1 is an example of the classical procedure. Entry 2 uses crown-ether catalysis. These reactions were conducted in the aromatic reactant as the solvent. In the study cited for Entry 2, it was found that substituted aromatic reactants such as toluene, anisole, and benzonitrile tended to give more *ortho* substitution product than expected on a statistical basis.¹⁸⁰ The nature of this directive effect does not seem to have been studied extensively. Entries 3 and 4 involve in situ decomposition of *N*-nitrosoamides. Entry 5 is a case of in situ nitrosation.

11.4.2. Substitution by the $S_{\text{RN}}1$ Mechanism

The mechanistic aspects of the $S_{\text{RN}}1$ reaction were discussed in Section 11.6 of Part A. The distinctive feature of the $S_{\text{RN}}1$ mechanism is an electron transfer between the nucleophile and the aryl halide.¹⁸¹ The overall reaction is normally a chain process.

Rosenberg, B. J. Garcia-Slanga, and G. W. Gokel, *J. Org. Chem.*, **49**, 1594 (1984).c. W. E. Bachmann and R. A. Hoffman, *Org. React.*, **2**, 249 (1944).d. H. Rapoport, M. Lick, and G. J. Kelly, *J. Am. Chem. Soc.*, **74**, 6293 (1952).e. J. I. G. Cadogan, *J. Chem. Soc.*, 4257 (1962).

A potential advantage of the $S_{RN}1$ mechanism is that it is not particularly sensitive to the nature of other aromatic ring substituents, although EWG substituents favor the nucleophilic addition step. For example, chloropyridines and chloroquinolines are excellent reactants.¹⁸² A variety of nucleophiles undergo the reaction, although not always in high yield. The nucleophiles that have been found to participate in

Chem.*, **42**, 2481 (1977); R. Beugelmans, M. Bois-Choussy, and B. Boudet, *Tetrahedron*, **24**, 4153 (1983).

$S_{RN}1$ substitution include ketone enolates,¹⁸³ ester enolates,¹⁸⁴ amide enolates,¹⁸⁵ 2,4-pentanedione dianion,¹⁸⁶ pentadienyl and indenyl carbanions,¹⁸⁷ phenolates,¹⁸⁸ diethyl phosphite anion,¹⁸⁹ phosphides,¹⁹⁰ and thiolates.¹⁹¹ The reactions are frequently initiated by light, which promotes the initiating electron transfer. As for other radical chain processes, the reaction is sensitive to substances that can intercept the propagation intermediates.

Scheme 11.12 provides some examples of the preparative use of the $S_{RN}1$ reaction. Entries 1 and 2 involve arylations of ketone enolates, whereas Entry 3 involves a dianion. Entry 4 is an example of a convenient preparation of arylphosphonates. Entry 5 is an example of application of the $S_{RN}1$ reaction to a chloropyridine.

(References for these problems will be found on page 1289.)

11.1. Give reagents and reaction conditions that would accomplish each of the following transformations. Multistep schemes are not necessary. Be sure to choose conditions that would lead to the desired isomer as the major product.

11.2. Suggest a short series of reactions that would be expected to transform the material on the right into the desired product shown on the left.

11.3. Write mechanisms that would account for the following reactions:

11.4. Predict the product(s) of the following reactions. If more than one product is expected, indicate which will be major and which will be minor.

11.5. Suggest efficient syntheses of *o*-, *m*-, and *p*-fluoropropiophenone from benzene and other necessary reagents.

11.6. Treatment of compound **6-1** in dibromomethane with one equivalent of aluminum bromide yields **6-2** as the only product in 78% yield. When three equivalents of

aluminum bromide are used, compounds **6-3** and **6-4** are obtained in a combined yield of 97%. Suggest an explanation for these observations.

- 11.7. Some data on the alkylation of naphthalene by 2-bromopropane using AlCl_3 under different conditions are given below. What factors are responsible for the differing product ratios for the two solvents, and why does the product ratio change with time?

Time (min)	$\alpha:\beta$ Product ratio	
	Solvent	
	CS_2	CH_3NO_2
5	4:96	83:17
15	2.5:97.5	74:26
45	2:98	70:30

- 11.8. Addition of a solution of bromine and potassium bromide to a solution of the carboxylate salt **8-1** results in the precipitation of a neutral compound having the formula $\text{C}_{11}\text{H}_{13}\text{BrO}_3$. Spectroscopic data show that the compound is nonaromatic. Suggest a structure and discuss the mechanistic significance of its formation.

- 11.9. Benzaldehyde, benzyl methyl ether, benzoic acid, methyl benzoate, and phenylacetic acid all undergo thallation initially in the *ortho* position. Explain this observation.
- 11.10. Reaction of 3,5,5-trimethyl-2-cyclohexenone with three equivalents of NaNH_2 in THF generates the corresponding enolate. When bromobenzene is added and the solution stirred for 4 h, the product **10-1** is isolated in 30% yield. Formulate a mechanism for this transformation.

- 11.11. When phenylacetonitrile is converted to its anion in the presence of excess LDA and then allowed to react with 2-bromo-4-methyl-1-methoxybenzene, the product contains both a benzyl and cyano substituent. Propose a mechanism for this reaction.

11.12. Suggest a reaction sequence that would permit synthesis of the following aromatic compounds from the starting material indicated on the right.

11.13. Aromatic substitution reactions are key steps in the multistep synthetic sequences that effect the following transformations. Suggest a sequence of reactions that could effect the desire syntheses.

- 11.14. The following intermediates in the synthesis of naturally occurring materials have been synthesized by reactions based on a benzyne intermediate. The benzyne precursor is shown. By retrosynthetic analysis identify an appropriate co-reactant that would form the desired compound.

- 11.15. Aryltrimethylsilanes has been found to be a useful complement to direct thallation in the preparation of arylthallium(III) intermediates. The thallium(III) replaces the silyl substituent and the scope of the reaction is expanded to include some EWGs, such as trifluoromethyl. How does the silyl group function in these systems?
- 11.16. The Pschorr reaction is a method of synthesis of phenanthrenes from diazotized Z-2-aminostilbenes. A traditional procedure involves heating with a copper catalyst. Improved yields are often observed, however, if the diazonium ion is treated with iodide ion. Suggest a mechanism for the iodide-catalyzed reaction.

- 11.17. When compound **17-1** is dissolved in FSO_3H at -78°C , NMR spectroscopy shows that a carbocation is formed. If the solution is then allowed to warm to -10°C , a different ion forms. The first ion gives compound **17-2** when

quenched with base, whereas the second ion gives **17-3**. What are the structures of the two carbocations, and why do they give different products on quenching?

- 11.18. Various phenols can be selectively hydroxymethylated at the *ortho* position by heating with paraformaldehyde and phenylboronic acid. An intermediate **18-1** having the formula $C_{14}H_{13}O_2B$ for the case shown can be isolated prior to the oxidation. Suggest a structure for the intermediate and comment on its role in the reaction.

- 11.19. The electrophilic cyclization of **19-1** and **19-2** gives two isomers, but with the unsubstituted reactant **19-3**, only a single stereoisomer is formed. Explain the origin of the isomers and the absence of isomer formation in the case of **19-3**.

- 11.20. Entry 5 in Scheme 11.4 is a step in the synthesis of the anticancer drug tamoxifen. Explain why the 2-phenylbutanoyl group is introduced in preference to a trifluoroacetyl group.

Oxidations

Introduction

This chapter is concerned with reactions that transform a functional group to a more highly oxidized derivative by removal of hydrogen and/or addition of oxygen. There are a great many oxidation methods, and we have chosen the reactions for discussion on the basis of their utility in synthesis. As the reactions are considered, it will become evident that the material in this chapter spans a broader range of mechanisms than most of the previous chapters. Owing to extent of this range, the chapter is organized according to the functional group transformation that is accomplished. This organization facilitates comparison of the methods available for effecting a given synthetic transformation. The major sections consider the following reactions: (1) oxidation of alcohols; (2) addition of oxygen at double bonds; (3) allylic oxidation; (4) oxidative cleavage of double bonds; (5) oxidative cleavage of other functional groups; (6) oxidations of aldehydes and ketones; and (7) oxidation at unfunctionalized positions. The oxidants are grouped into three classes: transition metal derivatives; oxygen, ozone, and peroxides; and other reagents.

12.1. Oxidation of Alcohols to Aldehydes, Ketones, or Carboxylic Acids

12.1.1. Transition Metal Oxidants

The most widely employed transition metal oxidants for alcohols are based on Cr(VI). The specific reagents are generally prepared from chromic trioxide, CrO_3 , or a dichromate salt, $[\text{Cr}_2\text{O}_7]^{2-}$. The form of Cr(VI) in aqueous solution depends upon concentration and pH; the $\text{p}K_1$ and $\text{p}K_2$ of H_2CrO_4 are 0.74 and 6.49, respectively. In dilute solution, the monomeric acid chromate ion $[\text{HCrO}_3]^-$ is the main species present; as concentration increases, the dichromate ion dominates.

In acetic acid, Cr(VI) is present as mixed anhydrides of acetic acid and chromic acid.¹

In pyridine, an adduct involving Cr–N bonding is formed.

The oxidation state of Cr in each of these species is (VI) and they are all powerful oxidants. The precise reactivity depends on the solvent and the chromium ligands, so substantial selectivity can be achieved by the choice of the particular reagent and conditions.

The general mechanism of alcohol oxidation involves coordination of the alcohol at chromium and a rate-determining deprotonation.

An important piece of evidence for this mechanism is the fact that a primary isotope effect is observed when the α -hydrogen is replaced by deuterium.² The Cr(IV) that is produced in the initial step is not stable and is capable of a further oxidation. It is believed that Cr(IV) is reduced to Cr(II), which is then oxidized by Cr(VI) generating Cr(V). This mechanism accounts for the overall stoichiometry of the reaction.³

Various experimental conditions have been used for oxidations of alcohols by Cr(VI) on a laboratory scale, and several examples are shown in Scheme 12.1. Entry 1 is an example of oxidation of a primary alcohol to an aldehyde. The propanal is distilled from the reaction mixture as oxidation proceeds, which minimizes overoxidation. For secondary alcohols, oxidation can be done by addition of an acidic aqueous solution containing chromic acid (known as *Jones' reagent*) to an acetone solution of the alcohol. Oxidation normally occurs rapidly, and overoxidation is minimal. In acetone solution, the reduced chromium salts precipitate and the reaction solution can be decanted. Entries 2 to 4 in Scheme 12.1 are examples of this method.

The chromium trioxide-pyridine complex is useful in situations when other functional groups might be susceptible to oxidation or the molecule is sensitive to acid.⁴ A procedure for utilizing the CrO₃-pyridine complex, which was developed by Collins,⁵ has been widely adopted. The CrO₃-pyridine complex is isolated and dissolved in dichloromethane. With an excess of the reagent, oxidation of simple alcohols is complete in a few minutes, giving the aldehyde or ketone in good yield. A procedure that avoids isolation of the complex can further simplify the experimental operations.⁶ Chromium trioxide is added to pyridine in dichloromethane. Subsequent addition of the alcohol to this solution results in oxidation in high yield. Other modifications for use of the CrO₃-pyridine complex have been developed.⁷ Entries 5 to 9 in Scheme 12.1 demonstrate the excellent results that have been reported using the CrO₃-pyridine complex in dichloromethane. Entries 5 and 6 involve conversion of primary alcohols to aldehydes, Entry 7 describes preparation of the reagent in situ, and Entry 8 is an example of application of these conditions to a primary alcohol. The conditions described in Entry 9 were developed to optimize the oxidation of sensitive carbohydrates. It was found that inclusion of 4A molecular sieves and a small amount of acetic acid accelerated the reaction.

Another very useful Cr(VI) reagent is pyridinium chlorochromate (PCC), which is prepared by dissolving CrO₃ in hydrochloric acid and adding pyridine to obtain a solid reagent having the composition CrO₃Cl·pyrH.⁸ This reagent can be used in amounts close to the stoichiometric ratio. Entries 10 and 11 are examples of the use of PCC. Reaction of pyridine with CrO₃ in a small amount of water gives pyridinium dichromate (PDC), which is also a useful oxidant.⁹ As a solution in DMF or a suspension in dichloromethane, this reagent oxidizes secondary alcohols to ketones. Allylic primary alcohols give the corresponding aldehydes. Depending upon the conditions, saturated primary alcohols give either an aldehyde or the corresponding carboxylic acid.

Although Cr(VI) oxidants are very versatile and efficient, they have one drawback, which becomes especially serious in larger-scale work: the toxicity and environmental hazards associated with chromium compounds. The reagents are used in stoichiometric or excess amount and the Cr(III) by-products must be disposed of safely.

Potassium permanganate, KMnO_4 , is another powerful transition metal oxidant, but it has found relatively little application in the oxidation of alcohols to ketones and aldehydes. The reagent is less selective than Cr(VI), and overoxidation is a problem. On the other hand, manganese(IV) dioxide is quite useful.¹⁰ This reagent, which is selective for allylic and benzylic alcohols, is prepared by reaction of Mn(II)SO_4 with KMnO_4 and sodium hydroxide. The precise reactivity of MnO_2 depends on its mode of preparation and the extent of drying.¹¹

Scheme 12.2 shows various types of alcohols that are most susceptible to MnO_2 oxidation. Entries 1 and 2 illustrate the application of MnO_2 to simple benzylic and allylic alcohols. In Entry 2, the MnO_2 was activated by azeotropic drying. Entry 3 demonstrates the application of the reagent to cyclopropylcarbinols. Entry 4 is an application to an acyloin. Entry 5 involves oxidation of a sensitive conjugated system.

A reagent system that is selective for allylic, benzylic, and cyclopropyl alcohols uses iodosobenzene in conjunction with a Cr(III)(salen) complex.¹²

Another recently developed oxidant is CrO_2 , a solid known as Magtrieve™ that is prepared commercially (for other purposes), which oxidizes allylic and benzylic alcohols in good yield.¹³ It is also reactive toward saturated alcohols. Because the solid remains ferromagnetic, it can be recovered by use of a magnet and can be reactivated by exposure to air at high temperature, making it environmentally benign.

Another possible alternative oxidant that has recently been investigated is an Fe(VI) species, potassium ferrate, K_2FeO_4 , supported on montmorillonite clay.¹⁴ This reagent gives clean, high-yielding oxidation of benzylic and allylic alcohols, but saturated alcohols are less reactive.

A catalytic system that extends the reactivity of MnO_2 to saturated secondary alcohols has been developed.¹⁵ This system consists of a Ru(II) salt, $\text{RuCl}_2(p\text{-cymene})_2$, and 2,6-di-*t*-butylbenzoquinone.

Ruthenium is the active oxidant and benzoquinone functions as an intermediary hydride transfer agent.

Another reagent that finds application of oxidations of alcohols to ketones is ruthenium tetroxide. The oxidations are typically carried out using a catalytic amount of the ruthenium source, e.g., RuCl_3 , with NaIO_4 or NaOCl as the stoichiometric oxidant.¹⁶ Acetonitrile is a favorable solvent because of its ability to stabilize the ruthenium species that are present.¹⁷ For example, the oxidation of **1** to **2** was successfully achieved with this reagent after a number of other methods failed.

Ref. 18

Ruthenium tetroxide is a potent oxidant, however, and it readily attacks carbon-carbon double bonds.¹⁹ Primary alcohols are oxidized to carboxylic acids, methyl ethers give methyl esters, and benzyl ethers are oxidized to benzoate esters.

Ref. 20

This reagent has been used in multistep syntheses to convert a tetrahydrofuran ring into a γ -lactone.

12.1.2. Other Oxidants

12.1.2.1. Oxidations Based Dimethyl Sulfoxide. A very useful group of procedures for oxidation of alcohols to ketones employs dimethyl sulfoxide (DMSO) and any one of several electrophilic reagents, such as dicyclohexylcarbodiimide (DCCI), acetic anhydride, trifluoroacetic anhydride (TFAA), oxalyl chloride, or sulfur trioxide.²² The original procedure involved DMSO and DCCI.²³ The mechanism of the oxidation involves formation of intermediate **A** by nucleophilic attack by DMSO on the carbodiimide, followed by reaction of the intermediate with the alcohol.²⁴ A proton transfer leads to an alkoxy-sulfonium ylide that is converted to product by an intramolecular proton transfer and elimination.

The activation of DMSO toward the addition step can be accomplished by other electrophiles. All of these reagents are believed to form a sulfoxonium species by electrophilic attack at the sulfoxide oxygen. The addition of the alcohol and the departure of the sulfoxide oxygen as part of a leaving group generates an intermediate comparable to **C** in the carbodiimide mechanism.

Preparatively useful procedures based on acetic anhydride,²⁵ trifluoroacetic anhydride,²⁶ and oxalyl chloride²⁷ have been developed. The last method, known as the *Swern oxidation*, is currently the most popular.

Scheme 12.3 gives some representative examples of these methods. Entry 1 is an example of the original procedure using DCCI. Entries 2 and 3 use SO_3 and $(\text{CH}_3\text{CO})_2\text{O}$, respectively, as the electrophilic reagents. Entry 3 is noteworthy in successfully oxidizing an alcohol without effecting the sensitive indole ring. Entry 4 is

an example of the use of a water-soluble carbodiimide as the activating reagent. The modified carbodiimide facilitates product purification by providing for easy removal of the urea by-product. Entries 5 and 6 are examples of the Swern procedure. Entry 7 uses TFAA as the electrophile. Entry 8, which uses the inexpensive reagent P_2O_5 as the electrophile, was conducted on a 60-g scale.

12.1.2.2. Oxidation by the Dess-Martin Reagent. Another reagent that has become important for laboratory synthesis is known as the *Dess-Martin reagent*,²⁸ which is a hypervalent iodine(V) compound.²⁹ The reagent is used in inert solvents such as chloroform or acetonitrile and gives rapid oxidation of primary and secondary alcohols. The by-product, *o*-iodosobenzoic acid, can be extracted with base and recycled.

12.1.2.3. Oxidations Using Oxoammonium Ions. Another oxidation procedure uses an oxoammonium ion, usually derived from the stable nitroxide tetramethylpiperidine nitroxide, TEMPO, as the active reagent.³¹ It is regenerated in a catalytic cycle using hypochlorite ion³² or NCS³³ as the stoichiometric oxidant. These reactions involve an intermediate adduct of the alcohol and the oxoammonium ion.

One feature of this oxidation system is that it can selectively oxidize primary alcohols in preference to secondary alcohols, as illustrated by Entry 2 in Scheme 12.5. The reagent can also be used to oxidize primary alcohols to carboxylic acids by a subsequent oxidation with sodium chlorite.³⁴ Entry 3 shows the selective oxidation of a primary alcohol in a carbohydrate to a carboxylic acid without affecting the secondary alcohol group. Entry 5 is a large-scale preparation that uses NaClO₂ in conjunction with bleach as the stoichiometric oxidant.

12.2. Addition of Oxygen at Carbon-Carbon Double Bonds

12.2.1. Transition Metal Oxidants

12.2.1.1. Dihydroxylation of Alkenes. The higher oxidation states of certain transition metals, particularly the permanganate ion and osmium tetroxide, are effective reagents for addition of two oxygen atoms at a carbon-carbon double bond. Under carefully controlled reaction conditions, potassium permanganate can effect conversion of alkenes to glycols. However, this oxidant is capable of further oxidizing the glycol with cleavage of the carbon-carbon bond. A cyclic manganese ester is an intermediate in these oxidations. Owing to the cyclic nature of this intermediate, the glycols are formed by *syn* addition.

Ketols are also observed as products of permanganate oxidation of alkenes. The ketols are believed to be formed as a result of oxidation of the cyclic intermediate.³⁵

Ruthenium tetroxide can also be used in the oxidation of alkenes. Conditions that are selective for formation of ketols have been developed.³⁶ Use of 1 mol % of RuCl_3 and five equivalents of KHSO_5 (Oxone[®]) in an ethyl acetate-acetonitrile-water mixture gives mainly hydroxymethyl ketones from terminal alkenes.

With aryl-substituted alkenes, the aryl ketone is the major product.

The mechanistic basis of this method depends on the use of excess peroxysulfate so that the major pathway leads to ketol rather than diol.

Permanganate ion can be used to oxidize acetylenes to diones.

A mixture of NaIO_4 and RuO_2 in a heterogeneous solvent system is also effective for this transformation.

The most widely used reagent for oxidation of alkenes to glycols is osmium tetroxide. Osmium tetroxide is a highly selective oxidant that gives glycols by a stereospecific *syn* addition.³⁹ The reaction occurs through a cyclic osmate ester that is formed by a [3 + 2] cycloaddition.⁴⁰

The reagent is toxic and expensive but these disadvantages are minimized by methods that use only a catalytic amount of osmium tetroxide. A very useful procedure involves an amine oxide such as morpholine-*N*-oxide as the stoichiometric oxidant.⁴¹

t-Butyl hydroperoxide,⁴² barium chlorate,⁴³ or potassium ferricyanide⁴⁴ can also be used as oxidants in catalytic procedures.

Scheme 12.6 provides some examples of oxidations of alkenes to glycols by both permanganate and osmium tetroxide. The oxidation by KMnO_4 in Entry 1 is done in cold aqueous solution. The reaction is very sensitive to the temperature control during the reaction. The reaction in Entry 2 was also done by the catalytic OsO_4 method using *N*-methylmorpholine-*N*-oxide in better (80%) yield. Note that the hydroxy groups are introduced from the less hindered face of the double bond. Entries 3 to 5 illustrate several of the catalytic procedures for OsO_4 oxidation. In each case the reaction is a stereospecific *syn* addition. Note also that in Entries 4 and 5 the double bond is conjugated with an EWG substituent, so the range of the reaction includes deactivated alkenes.

Osmium tetroxide oxidations can be highly enantioselective in the presence of chiral ligands. The most highly developed ligands are derived from the cinchona alkaloids dihydroquinine (DHQ) and dihydroquinidine (DHQD).⁴⁵ The most effective

ligands are dimeric derivatives of these alkaloids.⁴⁶ These ligands both induce high enantioselectivity and accelerate the reaction.⁴⁷ Potassium ferricyanide is usually used as the stoichiometric oxidant. Optimization of the reaction conditions permits rapid and predictable dihydroxylation of many types of alkenes.⁴⁸ The premixed catalysts are available commercially and are referred to by the trade name AD-mixTM. Several heterocyclic compounds including phthalazine (PHAL), pyrimidine (PYR), pyridazine (PYDZ), and diphenylpyrimidine (DPPYR) have been used as linking groups for the alkaloids.

Empirical analysis led to the predictive model for enantioselectivity shown in Figure 12.1.^{46c,49} The two alkaloids are of opposite chirality and give enantiomeric products. The commercial reagents are designated AD-mix- α and AD-mix- β . The configuration of the products can be predicted by a model based on the relative size of the substituent groups. *E*-Alkenes give the best fit to the binding pocket and give the highest reactivity and enantioselectivity.

There have been two computational studies of the basis for the catalysis and enantioselectivity. A study of the reaction of styrene with the (DHQD)₂PYDZ ligand was done using a hybrid DFT/MM protocol.⁵⁰ Two orientations of the styrene molecule were found that were about 3.0 kcal/mol more favorable than any of the others. These TSs are shown in Figure 12.2. Both these structures predict the observed *R*-configuration for the product. Most of the difference among the various structures is found in the MM terms and they are exothermic, that is, there are *net attractive forces involved in the binding of the reactant*. The second study used stilbene as the reactant and (DHQD)₂PHAL as the catalyst ligand.⁵¹ This study arrives at the TS shown in Figure 12.3. The two phenyl groups of stilbene occupy *both* of the sites found for the two low-energy TSs for styrene.

Scheme 12.7 gives some examples of enantioselective hydroxylations using these reagents. Entry 1 is an allylic ether with a terminal double bond. *para*-Substituted derivatives also gave high e.e. values, but some *ortho* substituents led to lower e.e. values. Entry 2 is one of several tertiary allylic alcohols that gave excellent results. Entry 3 is a *trans*-substituted alkene with rather large (but unbranched) substituents. The inclusion of methanesulfonamide, as in this example, has been found to be beneficial for di- and trisubstituted alkenes. It functions by speeding the hydrolysis of the osmate ester intermediate. The product in this case goes on to cyclize to the

Fig. 12.3. Transition structure for oxidation of stilbene by $(\text{DHQD})_2\text{PHAL-OsO}_4$ catalyst. Reproduced from *J. Am. Chem. Soc.*, **121**, 10186 (1999), by permission of the American Chemical Society.

observed lactone. This particular oxidation was also carried out with (DHQD)₂-PHAL, which gave the enantiomeric lactone. Entry 4 is an optimized oxidation of stilbene that was done on a 1-kg scale. Entry 5 is the dihydroxylation of geranyl acetate that shows selectivity for the 6,7-double bond. Entry 6 involves an unsaturated amide and required somewhat higher catalyst loading than normal. Entry 7 provided a starting material for the enantioselective synthesis of *S*-ibuprofen. The reaction in Entry 8 was used to prepare the lactone shown (and its enantiomer) as starting materials for enantioselective synthesis of several natural products. The furan synthesized in Entry 9 was used to prepare a natural material by a route involving eventual oxidation of the furan ring.

Various other chiral diamines have also been explored for use with OsO₄, some of which are illustrated in Scheme 12.8. They presumably function by forming hexacoordinate chelates with OsO₄. The reactant in Entry 3 also raises the issue of diastereoselectivity with respect to the allylic substituent. Normally, the dihydroxylation is *anti* toward such substituents.⁵² There are thus matched and mismatched combinations with the chiral osmium ligand. The *R,R*-diamine shown gives the matched combination and leads to high diastereoselectivity, as well as high enantioselectivity.

12.2.1.2. Transition Metal-Catalyzed Epoxidation of Alkenes. Other transition metal oxidants can convert alkenes to epoxides. The most useful procedures involve *t*-butyl hydroperoxide as the stoichiometric oxidant in combination with vanadium or

titanium compounds. The most reliable substrates for oxidation are allylic alcohols. The hydroxy group of the alcohol plays both an activating and stereodirecting role in these reactions. *t*-Butyl hydroperoxide and a catalytic amount of VO(acac) convert allylic alcohols to the corresponding epoxides in good yields.⁵³ The reaction proceeds through a complex in which the allylic alcohol is coordinated to vanadium by the hydroxy group. In cyclic alcohols, this results in epoxidation *cis* to the hydroxy group. In acyclic alcohols the observed stereochemistry is consistent with a TS in which the double bond is oriented at an angle of about 50° to the coordinated hydroxy group. This TS leads to diastereoselective formation of the *syn*-alcohol. This stereoselectivity is observed for both *cis*- and *trans*-disubstituted allylic alcohols.⁵⁴

The epoxidation of allylic alcohols can also be effected by *t*-butyl hydroperoxide and titanium tetrakisopropoxide. When enantiomerically pure tartrate ligands are included, the reaction is highly enantioselective. This reaction is called the *Sharpless asymmetric epoxidation*.⁵⁵ Either the (+) or (–) tartrate ester can be used, so either enantiomer of the desired product can be obtained.

The mechanism by which the enantioselective oxidation occurs is generally similar to that for the vanadium-catalyzed oxidations. The allylic alcohol serves to coordinate the substrate to titanium. The tartrate esters are also coordinated at titanium, creating a chiral environment. The active catalyst is believed to be a dimeric species, and the mechanism involves rapid exchange of the allylic alcohol and *t*-butylhydroperoxide at the titanium ion.

This method has proven to be an extremely useful means of synthesizing enantiomerically enriched compounds. Various improvements in the methods for carrying out the Sharpless oxidation have been developed.⁵⁶ The reaction can be done with catalytic amounts of titanium isopropoxide and the tartrate ligand.⁵⁷ This procedure uses molecular sieves to sequester water, which has a deleterious effect on both the rate and enantioselectivity of the reaction.

The orientation of the reactants is governed by the chirality of the tartrate ligand. In the TS an oxygen atom from the peroxide is transferred to the double bond. The enantioselectivity is consistent with a TS such as that shown below.⁵⁸

There has been a DFT (BLYP/6-31G*) study of the TS and its relationship to the enantioselectivity of the reaction.⁵⁹ The strategy used was to build up the model by successively adding components. First the titanium coordination sphere, including an alkene and peroxide group, was modeled (Figure 12.4a). In Figure 12.4b, the diol

ligand and allylic alcohol were added to the coordination sphere. Then the steric bulk associated with the hydroperoxide was added (Figure 12.4c), and finally the tartrate ligands were added (using formyl groups as surrogates; Figure 12.4d). This led successively to TSs of increasingly detailed structure. The energies were minimized to identify the most stable structure at each step. The key features of the final TS model are the following: (1) The peroxide-titanium interaction has a spiro, rather than

planar, arrangement in the TS for oxygen transfer. (2) The orientation of the alkyl group of the peroxide plays a key role in the enantioselectivity, which is consistent with the experimental observation that less bulky hydroperoxides give much lower enantioselectivity. (3) The C–O bond of the allylic alcohol bisects the Ti–O bond formed by the water and peroxy ligands. (4) The tartrate groups at the active catalytic center are in equatorial positions and do not coordinate to titanium. This implies a conformation flip of the diolate ring as part of the activation process, since the ester groups are in axial positions in the dimeric catalyst.

Visual models, additional information and exercises on Sharpless Epoxidation can be found in the Digital Resource available at: Springer.com/carey-sundberg.

Owing to the importance of the allylic hydroxy group in coordinating the reactant to the titanium, the structural relationship between the double bond and the hydroxy group is crucial. Homoallylic alcohols can be oxidized but the degree of enantioselectivity is reduced. Interestingly, the facial selectivity is reversed from that observed with allylic alcohols.⁶⁰ Compounds lacking a coordinating hydroxy group are not reactive under the standard reaction conditions.

Substituted allylic alcohols also exhibit diastereoselectivity. A DFT study has examined the influence of alkyl substituents in the allylic alcohol on the stereoselectivity.⁶¹ Alcohols **3a**, **3b**, and **3c** were studied. The catalytic entity was modeled by $\text{Ti}(\text{OH})_4\text{-CH}_3\text{OOH}$. This approach neglects the steric influence of the *t*-butyl and tartrate ester groups and focuses on the structural features of the allylic alcohols, which are placed on the catalytic core in their minimum energy conformation. Figure 12.5 shows these conformations. The TS structural parameters were derived from the Wu-Lai TS model (see Figure 12.4). The relative energies of the TSs leading to the *erythro* and *threo* products for each alcohol were compared (Figure 12.6). A solvent dielectric chosen to simulate CH_2Cl_2 was used. The general conclusion drawn from this study is that the reactant conformation is the critical feature determining the diastereoselectivity of the epoxidation.

In allylic alcohols with $A^{1,3}$ strain, the main product is *syn*. A methyl substituent at R^4 leads to the methyl group being positioned *anti* to the complexed oxidant. If R^4 is hydrogen, a TS with the methyl group in an “inside” position is favored, as shown in Figure 12.6.

The two TSs for **3a** are shown in Figure 12.7. **TS A** also has a more favorable orientation of the spiro ring structure. The ideal angle is 90° , at which point the two rings are perpendicular. This angle is 78.2° in **TS A** and 36.2° in **TS B**. **TS A** has a $\text{O}(1)\text{--C}(2)\text{--C}(3)\text{--C}(4)$ angle of 35.6° , **TS B** has a corresponding angle of 96.1° . Based on the reactant conformational profile, this will introduce about 0.7 kcal more

Scheme 12.9 gives some examples of enantioselective oxidation of allylic alcohols. Entry 1 is a representative procedure, as documented in an *Organic Syntheses* preparation. The reaction in Entry 2 was used to prepare a starting material for synthesis of leukotriene C-1. Entry 3 is an example incorporating the use of molecular sieves. The reaction in Entry 4 was the departure point in a synthesis of part of the polyether antibiotic X-206. Entry 5 is another example of the procedure using molecular sieves. The catalyst loading in this reaction is 5%. The reaction in Entry 6 is diastereoselective for the *anti* isomer. Entry 7 also shows a case of diastereoselectivity, in this instance with respect to the 4-methyl group. Note that both of these reactions involve oxidation of the alkene from the same face, although they differ in configuration at C(4). Thus, the enantioselectivity is under reagent control.

Several catalysts that can effect enantioselective epoxidation of unfunctionalized alkenes have been developed, most notably manganese complexes of diimines derived from salicylaldehyde and chiral diamines (salens).⁶²

These catalysts are used in conjunction with a stoichiometric amount of an oxidant and the active oxidant is believed to be an oxo Mn(V) species. The stoichiometric oxidants that have been used include NaOCl,⁶³ periodate,⁶⁴ and amine oxides.⁶⁵ Various other

chiral salen-type ligands have also been explored.⁶⁶ These epoxidations are not always stereospecific with respect to the alkene geometry, which is attributed to an electron transfer mechanism that involves a radical intermediate.

chemoselectivity for the 4,5-double bond in a dienoate ester. This case also illustrates the occurrence of isomerization during the epoxidation. Entry 4 is a step in the enantioselective synthesis of CDP840, a phosphodiesterase inhibitor. The reaction in Entry 5 provided a starting material for the synthesis of the DNA-alkylating antitumor agent CC-1065.

12.2.2. Epoxides from Alkenes and Peroxidic Reagents

12.2.2.1. Epoxidation by Peroxy Acids and Related Reagents. The most general reagents for conversion of simple alkenes to epoxides are peroxycarboxylic acids.⁶⁷ *m*-Chloroperoxybenzoic acid⁶⁸ (MCPBA) is a particularly convenient reagent. The magnesium salt of monoperoxyphthalic acid is an alternative.⁶⁹ Potassium hydrogen peroxysulfate, which is sold commercially as Oxone®, is a convenient reagent for epoxidations that can be done in aqueous methanol.⁷⁰ Peroxyacetic acid, peroxybenzoic acid, and peroxytrifluoroacetic acid have also been used frequently for epoxidation. All of the peroxycarboxylic acids are potentially hazardous materials and require appropriate precautions.

It has been demonstrated that ionic intermediates are not involved in the epoxidation reaction. The reaction rate is not very sensitive to solvent polarity.⁷¹ Stereospecific *syn* addition is consistently observed. The oxidation is therefore believed to be a concerted process. A representation of the transition structure is shown below.

The rate of epoxidation of alkenes is increased by alkyl groups and other ERG substituents and the reactivity of the peroxy acids is increased by EWG substituents.⁷² These structure-reactivity relationships demonstrate that the peroxyacid acts as an electrophile in the reaction. Decreased reactivity is exhibited by double bonds that are conjugated with strongly electron-attracting substituents, and more reactive peroxyacids, such as trifluoroperoxyacetic acid, are required for oxidation of such compounds.⁷³ Electron-poor alkenes can also be epoxidized by alkaline solutions of

hydrogen peroxide or *t*-butyl hydroperoxide. A quite different mechanism, involving conjugate nucleophilic addition, operates in this case.⁷⁴

There have been a number of computational studies of the epoxidation reaction. These studies have generally found that the hydrogen-bonded peroxy acid is approximately perpendicular to the axis of the double bond, giving a spiro structure.⁷⁵ Figure 12.8 shows TS structures and E_a values based on B3LYP/6-31G* computations. The E_a trend is as expected for an electrophilic process: $\text{OCH}_3 < \text{CH}_3 \sim \text{CH}=\text{CH}_2 < \text{H} < \text{CN}$. Similar trends were found in MP4/6-31G* and QCISD/6-31G* computations.

The stereoselectivity of epoxidation with peroxycarboxylic acids has been well studied. Addition of oxygen occurs preferentially from the less hindered side of the molecule. Norbornene, for example, gives a 96:4 *exo:endo* ratio.⁷⁶ In molecules where two potential modes of approach are not very different, a mixture of products is formed.

⁷⁶ H. Kwart and T. Takeshita, *J. Org. Chem.*, **28**, 670 (1963).

For example, the unhindered exocyclic double bond in 4-*t*-butylmethylenecyclohexane gives both stereoisomeric products.⁷⁷

Hydroxy groups exert a directive effect on epoxidation and favor approach from the side of the double bond closest to the hydroxy group.⁷⁸ Hydrogen bonding between the hydroxy group and the reagent evidently stabilizes the TS.

This is a strong directing effect that can exert stereochemical control even when steric effects are opposed. Entries 4 and 5 in Scheme 12.11 illustrate the hydroxy-directing effect. Other substituents capable of hydrogen bonding, in particular amides, also can exert a *syn*-directing effect.⁷⁹

The hydroxy-directing effect has been studied computationally, as the hydrogen bond can have several possible orientations.⁸⁰ Studies on 2-propen-1-ol show the same preference for the spiro TS as for unfunctionalized alkenes. There is a small preference for hydrogen bonding to a peroxy oxygen, as opposed to the carbonyl oxygen. The TSs for conformations of 2-propen-1-ol that are not hydrogen-bonded are 2–3 kcal/mol higher in energy than the best of the hydrogen-bonded structures. For substituted allylic alcohols, $A^{1,2}$ and $A^{1,3}$ strain comes into play. Figure 12.9 shows the structures and relative energies of the four possible TSs for prop-2-en-1-ol. The *syn,exo* structure with hydrogen-bonding to the transferring oxygen is preferred to the *endo* structure, in which the hydrogen-bonding is to the carbonyl oxygen.

Torsional effects are important in cyclic systems. A PM3 study of the high stereoselectivity of compounds **4a–d** found torsional effects to be the major difference between the diastereomeric TSs.⁸¹ The computed TSs for **4a** are shown in Figure 12.10. The structures all show similar stereoselectivity, regardless of the presence and nature of a 3-substituent.

Even in the absence of a 3-substituent (**4a**, **4b**) and with only a small 4-methyl group (**4a**), the stereoselectivity is high. The preference arises from the staggered relationship between the forming C–O bond and the axial allylic hydrogen.

Fig. 12.10. Comparison of *trans*- and *cis*-oriented transition structures for epoxidation of 1-methyl-1,2-dihydronaphthalene. Reproduced from *J. Org. Chem.*, **63**, 6973 (1998), by permission of the American Chemical Society.

A process that is effective for epoxidation and avoids acidic conditions involves reaction of an alkene, a nitrile, and hydrogen peroxide.⁸² The nitrile and hydrogen peroxide react, forming a peroxyimidic acid, which epoxidizes the alkene, by a mechanism similar to that for peroxyacids. An important contribution to the reactivity of the peroxyimidic acid comes from the formation of the stable amide carbonyl group.

At least in some cases, the hydroxy-directing effect also operates for this version of the reaction.

Ref. 83

Scheme 12.11 gives some examples of epoxidation using peroxyacids and related reagents. Entry 1 shows standard epoxidation conditions applied to styrene. The reaction in Entry 2 uses typical epoxidation conditions and also illustrates the approach from the less hindered face of the molecule. In Entry 3, the selectivity for the more-substituted double bond was used to achieve regioselectivity. Entries 4 and 5 illustrate stereochemical control by hydroxy participation. The reaction in Entry 6 is an example of diastereoselectivity, most likely due to hydrogen bonding by the amide group. Entries 7 and 8 are cases of application of nucleophilic peroxidation conditions to alkenes conjugated with EWG substituents. In Entry 9, the more reactive trifluoroperoxyacetic acid was used to oxidize a deactivated double bond. Entry 10 is an example of use of the peroxyimidic acid conditions.

There is interest in being able to use H_2O_2 directly as an epoxidizing reagent because it is the ultimate source of most peroxides. The reactivity of H_2O_2 is substantially enhanced in hexafluoro-2-propanol (HFIP) and other polyfluorinated alcohols such as nonafluoro-*t*-butanol.⁸⁴ Either 30 or 60% H_2O_2 can oxidize alkenes to epoxides in these solvents. The system shows the normal trend of higher reactivity for more-substituted alkenes. The activation is attributed to polarization of the H_2O_2 by hydrogen bonding with the β -fluoroalcohols. The fluoro substituents also increase the acidity of the hydroxy group.

A variety of electrophilic reagents have been examined with the objective of activating H_2O_2 to generate a good epoxidizing agent. In principle, any species that can convert one of the hydroxy groups to a good leaving group can generate a reactive epoxidizing reagent.

In practice, promising results have been obtained for several systems. For example, fair to good yields of epoxides are obtained when a two-phase system consisting of alkene and ethyl chloroformate is stirred with a buffered basic solution of hydrogen peroxide. The active oxidant is presumed to be *O*-ethyl peroxydicarboxylic acid.⁸⁵

Although these reagent combinations are not as generally useful as the peroxycarboxylic acids, they serve to illustrate that epoxidizing activity is not unique to the peroxyacids.

12.2.2.2. Epoxidation by Dioxirane Derivatives. Another useful epoxidizing agent is dimethyldioxirane (DMDO),⁸⁶ which is generated by in situ reaction of acetone and peroxydisulfate in buffered aqueous solution. Distillation gives about a 0.1 *M* solution of DMDO in acetone.⁸⁷

Higher concentrations of DMDO can be obtained by extraction of a 1:1 aqueous dilution of the distillate by CH_2Cl_2 , CHCl_3 , or CCl_4 .⁸⁸ Another method involves in situ generation of DMDO under phase transfer conditions.⁸⁹

The yields and rates of oxidation by DMDO under these in situ conditions depend on pH and other reaction parameters.⁹⁰

Various computational models agree that the reaction occurs by a concerted mechanism.⁹¹ Comparison between epoxidation by peroxy acids and dioxiranes suggests that they have similar transition structures.

Kinetics and isotope effects are consistent with this mechanism.⁹² The reagent is electrophilic in character and reaction is facilitated by ERG substituents in the alkene. A B3LYP/6-31G* computation found the transition structures and E_a values shown in Figure 12.11.

Similarly to peroxycarboxylic acids, DMDO is subject to *cis* or *syn* stereoselectivity by hydroxy and other hydrogen-bonding functional groups.⁹³ However a study of several substituted cyclohexenes in $\text{CH}_3\text{CN}-\text{H}_2\text{O}$ suggested a dominance by steric effects. In particular, the hydroxy groups in cyclohex-2-enol and

3-methylcyclohex-2-enol were not very strongly *syn* directing.⁹⁴ The hydroxylic solvent may minimize any directive effect by competing hydrogen bonding.⁹⁵

Directing effects have also been attributed to more remote substituents, as, e.g., a urea NH.

Several disubstituted 3,4-dimethylcyclobutenes show *syn* selectivity. The mesylate groups were strongly *syn* directive, with the hydroxy, methoxy, and acetoxy groups being somewhat less so.⁹⁷ The same groups were even more strongly *syn* directing with MCPBA. The effects are attributed to an attractive electrostatic interaction of the relatively positive methylene hydrogens and the oxygens of the dioxirane and peroxy acid.

X	DMDO	MCPBA
OH	67:33	82:18
OCH ₃	62:38	76:24
O ₂ CCH ₃	68:32	69:31
OSO ₂ CH ₃	79:21	87:13

For other substituents, both steric and dipolar factors seem to have an influence and several complex reactants have shown good stereoselectivity, although the precise origin of the stereoselectivity is not always evident.⁹⁸

Other ketones besides acetone can be used for in situ generation of dioxiranes by reaction with peroxysulfate or another suitable peroxide. More electrophilic ketones give more reactive dioxiranes. 3-Methyl-3-trifluoromethyldioxirane is a more reactive analog of DMDO.⁹⁹ This reagent, which is generated in situ from 1,1,1-trifluoroacetone, can oxidize less reactive compounds such as methyl cinnamate.

Ref. 100

Hexafluoroacetone and hydrogen peroxide in buffered aqueous solution can epoxidize alkenes and allylic alcohols.¹⁰¹ *N,N*-Dialkylpiperidin-4-one salts are also good catalysts for epoxidation.¹⁰² The polar effect of the quaternary nitrogen enhances the

illustrates the use of a piperidone salt for in situ generation of a dioxirane. The long alkyl chain imparts phase transfer capability to the ketone. The dioxirane is generated in the aqueous phase but can carry out the epoxidation in the organic phase. Entries 3 to 5 are examples of stereoselective epoxidations. In each case, high stereoselectivity is observed in the presence of nearby functional groups. The exact origins of the stereoselectivity are not clear.

A number of chiral ketones have been developed that are capable of enantioselective epoxidation via dioxirane intermediates.¹⁰⁴ Scheme 12.13 shows the structures of some chiral ketones that have been used as catalysts for enantioselective epoxidation. The BINAP-derived ketone shown in Entry 1, as well as its halogenated derivatives, have shown good enantioselectivity toward di- and trisubstituted alkenes.

The fluorinated tropones **H** and **I** also show good reactivity and are enantioselective in favorable cases, but show considerable dependence on reactant structure. The carbohydrate structures **J** and **K** also benefit from a polar effect of the adjacent oxygens and give good enantioselectivity with a variety of *trans* di- and trisubstituted alkenes. The oxazolidinone derivative **K** also shows good enantioselectivity toward *cis*-substituted and terminal alkenes. Transition structures **TS J** and **TS K** have been suggested for epoxidation by these ketones. It has been noted that alkenes with conjugated π systems have a preferred orientation toward the oxazolidinone ring.

These ketones can also be used in kinetic resolutions.¹⁰⁷ The carbohydrate-derived ketones have been used in conjunction with acetonitrile and H_2O_2 . The reactions are believed to proceed through dioxiranes generated by a catalytic cycle involving a peroxyimide acid.¹⁰⁸

12.2.3. Subsequent Transformations of Epoxides

Epoxides are useful synthetic intermediates and the conversion of an alkene to an epoxide is often part of a more extensive molecular transformation.¹⁰⁹ In many instances advantage is taken of the reactivity of the epoxide ring toward nucleophiles to introduce additional functionality. Since epoxide ring opening is usually stereospecific, such reactions can be used to establish stereochemical relationships between adjacent substituents. Such two- or three-step operations can accomplish specific oxidative transformations of an alkene that may not be easily accomplished in a single step. Scheme 12.14 provides a preview of the type of reactivity to be discussed.

12.2.3.1. Nucleophilic and Solvolytic Ring Opening. Epoxidation may be preliminary to solvolytic or nucleophilic ring opening in synthetic sequences. Epoxides can undergo ring opening under either basic or acidic conditions. Base-catalyzed reactions, in which the nucleophile provides the driving force for ring opening, usually involve breaking the epoxide bond at the less-substituted carbon, since this is the position most accessible to nucleophilic attack.¹¹⁰ These reactions result in an *anti* relationship between the epoxide oxygen and the nucleophile. The situation in acid-catalyzed reactions is more complex. The bonding of a proton to the oxygen weakens the C—O bonds and facilitates rupture by weak nucleophiles. If the C—O bond is largely intact at the TS, the nucleophile becomes attached to the less-substituted position for the same steric reasons that were cited for nucleophilic ring opening. If, on the other hand, C—O rupture is more complete at the TS, the opposite orientation is observed. This change in regiochemistry results from the ability of the more-substituted carbon to better stabilize the developing positive charge.

Scheme 12.14. Synthetic Transformations of Epoxides

A. Epoxidation followed by nucleophilic ring opening

B. Epoxidation followed by reductive ring opening

C. Epoxidation followed by rearrangement to a carbonyl compound

D. Epoxidation followed by ring opening to an allyl alcohol

¹¹⁰ R. E. Parker and N. S. Isaacs, *Chem. Rev.*, **59**, 737 (1959).

When simple aliphatic epoxides such as propylene oxide react with hydrogen halides, the dominant product has the halide at the less-substituted primary carbon.¹¹¹

Substituents that further stabilize a carbocation intermediate lead to reversal of the mode of addition.¹¹² The case of styrene oxide hydrolysis has been carefully examined. Under acidic conditions, the bond breaking is exclusively at the benzylic position. Under basic conditions, ring opening occurs at both epoxide carbons.¹¹³ Styrene also undergoes highly regioselective ring opening in the presence of Lewis acids. For example, methanolysis is catalyzed by SnCl_4 and occurs with greater than 95% attack at the benzyl carbon and with high inversion.¹¹⁴ The stereospecificity indicates a concerted nucleophilic opening of the complexed epoxide.

In cyclic systems, ring opening gives the diaxial diol.

Ref. 115

Under some circumstances, acid-catalyzed ring opening of 2,2-disubstituted epoxides by sulfuric acid in dioxane goes with high *inversion* at the tertiary center.¹¹⁶

Ref. 117

Ref. 118

Under somewhat modified conditions (H_2SO_4 on silica), this reaction has been successfully applied to a complex alkaloid structure.¹¹⁹

Recently a number of procedures for epoxide ring opening that feature the oxyphilic Lewis acids, including lanthanides, have been developed. LiClO_4 , LiO_3SCF_3 , $\text{Mg}(\text{ClO}_4)_2$, $\text{Zn}(\text{O}_3\text{SCF}_3)_2$, and $\text{Yb}(\text{O}_3\text{SCF}_3)_3$ have been shown to catalyze epoxide ring opening.¹²⁰ The cations catalyze *anti* addition of amines at the less-substituted carbon, which is consistent with a Lewis acid–assisted nucleophilic ring opening.

Styrene oxide gives mixtures of C- α and C- β attack, as a result of competition between the activated benzylic site and the primary site.

The same salts can be used to catalyze ring opening by other nucleophiles such as azide ion¹²¹ and cyanide ion.¹²²

A variety of reaction conditions have been developed for nucleophilic ring opening by cyanide.¹²³ Heating an epoxide with acetone cyanohydrin (which serves as the cyanide source) and triethylamine leads to ring opening at the less-substituted position.

Trimethylsilyl cyanide in conjunction with KCN and a crown ether also results in nucleophilic ring opening.

Diethylaluminum cyanide can also be used for preparation of β -hydroxynitriles.

Similarly, diethylaluminum azide gives β -azido alcohols. The epoxide of 1-methylcyclohexene gives the tertiary azide, indicating that the regiochemistry is controlled by bond cleavage, but with diaxial stereoselectivity.

Epoxides of allylic alcohols exhibit chelation-controlled regioselectivity.¹²⁸

Scheme 12.15 gives some examples of both acid-catalyzed and nucleophilic ring openings of epoxides. Entries 1 and 2 are cases in which epoxidation and solvolysis are carried out without isolation of the epoxide. Both cases also illustrate the preference for *anti* stereochemistry. The regioselectivity in Entry 3 is indicative of dominant bond cleavage in the TS. The reaction in Entry 4 was studied in a number of solvents. The product results from net *syn* addition as a result of phenonium ion participation. The *cis*-epoxide also gives mainly the *syn* product, presumably via isomerization to the

more stable *trans* isomer by reversible ring opening and formation of the more stable *trans*-phenonium ion.

Entry 5 is an example of synthetic application of acid-catalyzed ring opening.

Entries 6 to 11 are examples of nucleophilic ring opening. Each of these entries displays the expected preference for reaction at the less hindered carbon. Entries 8 and 9 involve metal ion catalysis. Entry 11, which involves carbon-carbon bond formation, was part of a synthesis of epothilone A.

12.2.3.2. Reductive Ring Opening. Epoxides can be reduced to saturated alcohols. Lithium aluminum hydride acts as a nucleophilic reducing agent and the hydride is added at the less-substituted carbon atom of the epoxide ring. Substituted cyclohexene oxides prefer diaxial ring opening. A competing process, which accounts for about 10% of the product in the examples shown, involves rearrangement to the cyclohexanone (see below) by hydride shift, followed by reduction.¹²⁹

¹²⁹ B. Rickborn and J. Quartucci, *J. Org. Chem.*, **29**, 3185 (1964); B. Rickborn and W. Z. Lamke, II, *J. Org. Chem.*, **32**, 537 (1967).

The *trans*-3-methyl isomer appears to react through two conformers, with the axial methyl conformer giving *trans*-2-methylcyclohexanol.

Lithium triethylborohydride is more reactive than LiAlH_4 and is superior for epoxides that are resistant to reduction.¹³⁰ Reduction by dissolving metals, such as lithium in ethylenediamine,¹³¹ also gives good yields. Di-*i*-butylaluminum hydride also reduces epoxides. 1,2-Epoxyoctane gives 2-octanol in excellent yield, and styrene oxide gives a 1:6 mixture of the secondary and primary alcohols.¹³² This relationship indicates that nucleophilic ring opening controls the regiochemistry for 1,2-epoxyoctane but that ring cleavage at the benzylic position is the major factor for styrene oxide.

Diborane in THF reduces epoxides, but the yields are low, and other products are formed by pathways that result from the electrophilic nature of diborane.¹³³ Better yields are obtained when BH_4^- is included in the reaction system, but the electrophilic nature of diborane is still evident because the dominant product results from addition of the hydride at the more-substituted carbon.¹³⁴

The overall transformation of alkenes to alcohols that is accomplished by epoxidation and reduction corresponds to alkene hydration. Assuming a nucleophilic ring opening by hydride addition at the less-substituted carbon, the reaction corresponds to the Markovnikov orientation. This reaction sequence is therefore an alternative to the hydration methods discussed in Chapter 4 for converting alkenes to alcohols.

12.2.3.3. Rearrangement of Epoxides to Carbonyl Compounds. Epoxides can be isomerized to carbonyl compounds by Lewis acids.¹³⁵ This reaction is closely related to the pinacol rearrangement (see p. 883). The epoxide oxygen functions as the leaving group and becomes the oxygen in the new carbonyl group.

Carbocation intermediates are involved and the structure and stereochemistry of the product are determined by the factors that govern substituent migration in the carbocation. Clean, high-yield reactions can be expected only where structural or conformational factors promote a selective rearrangement. Boron trifluoride is frequently used as the reagent.

Ref. 136

Catalytic amounts of Bi(O₃SCF₃)₃ also promote this rearrangement.¹³⁷

Bulky diaryloxymethylaluminum reagents are also effective for this transformation.

Ar = 2,6-di-*t*-butyl-4-bromophenyl

Ref. 138

This reagent is selective for rearrangement to aldehydes in cases where BF₃, SnCl₄, and SbF₅ give mixtures.¹³⁹

¹³⁸ K. Maruoka, S. Nagahara, T. Ooi, and H. Yamamoto, *Tetrahedron Lett.*, **30**, 5607 (1989).

¹³⁹ K. Maruoka, T. Ooi, and H. Yamamoto, *Tetrahedron*, **48**, 3303 (1992); K. Maruoka, N. Murase, R. Bureau, T. Ooi, and H. Yamamoto, *Tetrahedron*, **50**, 3663 (1994).

This selectivity is attributed to the steric bulk of the aluminum reagent favoring the migration of the larger alkyl group. The same selectivity pattern is observed with unbranched substituents.

Double bonds having oxygen and halogen substituents are susceptible to epoxidation, and the reactive epoxides that are generated serve as intermediates in some useful synthetic transformations in which the substituent migrates to the other carbon of the original double bond. Vinyl chlorides furnish haloepoxides that can rearrange to α -haloketones.

Ref. 140

When this reaction sequence is applied to enol esters or enol ethers, the result is α -oxygenation of the starting carbonyl compound. Enol acetates form epoxides that rearrange to α -acetoxyketones.

Ref. 141

¹⁴⁰. R. N. McDonald and T. E. Tabor, *J. Am. Chem. Soc.*, **89**, 6573 (1967).

¹⁴¹. K. L. Williamson, J. I. Coburn, and M. F. Herr, *J. Org. Chem.*, **32**, 3934 (1967).

The stereochemistry of the reaction depends on the Lewis acid. Protic acids favor retention of configuration, as does TMSOTf. Most metal halides give mixtures of inversion and retention, but $\text{Al}(\text{CH}_3)_3$ gives dominant inversion.¹⁴² Inversion is suggestive of direct carbonyl group participation.

The reaction can also be done thermally. The stereochemistry of the thermal rearrangement of the acetoxy epoxides involves inversion at the carbon to which the acetoxy group migrates,¹⁴³ and reaction probably proceeds through a cyclic TS.

A more synthetically reliable version of this reaction involves epoxidation of silyl enol ethers. Epoxidation of the silyl enol ethers followed by aqueous workup gives α -hydroxyketones and α -hydroxyaldehydes.¹⁴⁴

The epoxidation can be done either with peroxy acids or DMDO. In the former case, the rearrangement is catalyzed by the carboxylic acid that is formed, whereas with DMDO, the intermediate epoxides can sometimes be isolated.

¹⁴⁴. A. Hassner, R. H. Reuss, and H. W. Pinnick, *J. Org. Chem.*, **40**, 3427 (1975).

Ref. 145

Ref. 146

The oxidation of silyl enol ethers with the osmium tetroxide–amine oxide combination also leads to α -hydroxyketones in generally good yields.¹⁴⁷

Epoxides derived from vinylsilanes are converted by mildly acidic conditions into ketones or aldehydes.¹⁴⁸

The regioselective ring opening of the silyl epoxides is facilitated by the stabilizing effect that silicon has on a positive charge in the β -position. This facile transformation permits vinylsilanes to serve as the equivalent of carbonyl groups in multistep synthesis.¹⁴⁹

12.2.3.4. Base-Catalyzed Ring Opening of Epoxides. Base-catalyzed ring opening of epoxides provides a route to allylic alcohols.¹⁵⁰

¹⁴⁷ J. P. McCormick, W. Tomasik, and M. W. Johnson, *Tetrahedron Lett.*, 607 (1981).

¹⁴⁸ G. Stork and E. Colvin, *J. Am. Chem. Soc.*, **93**, 2080 (1971).

¹⁴⁹ G. Stork and M. E. Jung, *J. Am. Chem. Soc.*, **96**, 3682 (1974).

¹⁵⁰ J. K. Crandall and M. Appar, *Org. React.*, **29**, 345 (1983).

Strongly basic reagents, such as the lithium salt of dialkylamines, are required to promote the reaction. The stereochemistry of the ring opening has been investigated by deuterium labeling. A proton *cis* to the epoxide ring is selectively removed.¹⁵¹

A TS represented by structure **L** accounts for this stereochemistry. Such an arrangement is favored by ion pairing that would bring the amide anion and lithium cation into close proximity. Simultaneous coordination of the lithium ion at the epoxide results in a *syn* elimination.

Among other reagents that effect epoxide ring opening are diethylaluminum 2,2,6,6-tetramethylpiperide and magnesium *N*-cyclohexyl-*N*-(*i*-propyl)amide.

Ref. 152

Ref. 153

These reagents are appropriate even for very sensitive molecules. Their efficacy is presumably due to the Lewis acid effect of the aluminum and magnesium ions. The hindered nature of the amide bases also minimizes competition from nucleophilic ring opening.

¹⁵². A. Yasuda, S. Tanaka, K. Oshima, H. Yamamoto, and H. Nozaki, *J. Am. Chem. Soc.*, **96**, 6513 (1974).

¹⁵³. E. J. Corey, A. Marfat, J. R. Falck, and J. O. Albright, *J. Am. Chem. Soc.*, **102**, 1433 (1980).

Epoxides can also be converted to allylic alcohols using electrophilic reagents. The treatment of epoxides with trialkyl silyl iodides and an organic base gives the silyl ether of the corresponding allylic alcohols.¹⁵⁴

Similar ring openings have been achieved using trimethylsilyl triflate and 2,6-di-*t*-butylpyridine.¹⁵⁵

Each of these procedures for epoxidation and ring opening is the equivalent of an allylic oxidation of a double bond with migration of the double bond.

In Section 12.3, other means of effecting this transformation are described.

12.3. Allylic Oxidation

12.3.1. Transition Metal Oxidants

Carbon-carbon double bonds, apart from being susceptible to addition of oxygen or cleavage, can also react at allylic positions. Synthetic utility requires that there be good selectivity between the possible reactions. Among the transition metal oxidants, the CrO_3 -pyridine reagent in methylene chloride¹⁵⁶ and a related complex in which 3,5-dimethylpyrazole replaces pyridine¹⁵⁷ are the most satisfactory for allylic oxidation.

Ref. 158

Several pieces of mechanistic evidence implicate allylic radicals or cations as intermediates in these oxidations. Thus ^{14}C in cyclohexene is distributed in the product cyclohexenone indicating that a symmetrical allylic intermediate is involved at some stage.¹⁵⁹

¹⁵⁹. K. B. Wiberg and S. D. Nielsen, *J. Org. Chem.*, **29**, 3353 (1964).

In many allylic oxidations, the double bond is found in a position indicating that an allylic transposition occurs during the oxidation.

Detailed mechanistic understanding of the allylic oxidation has not been developed. One possibility is that an intermediate oxidation state of Cr, specifically Cr(IV), acts as the key reagent by abstracting hydrogen.¹⁶⁰

Several catalytic systems based on copper can also achieve allylic oxidation. These reactions involve induced decomposition of peroxy esters (see Part A, Section 11.1.4). When chiral copper ligands are used, enantioselectivity can be achieved. Table 12.1 shows some results for the oxidation of cyclohexene under these conditions.

12.3.2. Reaction of Alkenes with Singlet Oxygen

Among the oxidants that add oxygen at carbon-carbon double bonds is singlet oxygen.¹⁶¹ For most alkenes this reaction proceeds with the removal of an allylic

Table 12.1. Enantioselective Copper-Catalyzed Allylic Oxidation of Cyclohexene

hydrogen and shift of the double bond to provide an allylic hydroperoxide as the initial product.

The allylic hydroperoxides generated by singlet oxygen oxidation are normally reduced to the corresponding allylic alcohol. The net synthetic transformation is then formation of an allylic alcohol with transposition of the double bond.

A number of methods of generating singlet oxygen are summarized in Scheme 12.16. Singlet oxygen is usually generated from oxygen by dye-sensitized photoexcitation. Porphyrins are also often used as sensitizers. An alternative chemical means of generating $^1\text{O}_2$ involves the reaction of hydrogen peroxide with sodium hypochlorite (Entry 2). The method in Entry 3 involves formation of unstable trioxaphosphetane intermediates from O_3 and phosphine or phosphate esters. The adducts are formed at low temperature (-70°C) and decomposition with generation of singlet oxygen occurs at about -35°C . The peroxide intermediate in Entry 4 is formed by photolytic addition of oxygen to diphenylanthracene and reacts at around 80°C to generate $^1\text{O}_2$. The method in Entry 5 involves formation of an unstable precursor of $^1\text{O}_2$, a trialkylsilyl hydrotrioxide. The half-life of the adduct is roughly 2.5 min at -60°C .

Singlet oxygen decays to the ground state triplet at a rate that is strongly dependent on the solvent.¹⁶² Measured half-lives range from about 700 μ s in carbon tetrachloride to 2 μ s in water. The choice of solvent can therefore have a pronounced effect on the efficiency of oxidation; the longer the singlet state lifetime, the more likely it is that reaction with the alkene can occur.

The reactivity order of alkenes is that expected for attack by an electrophilic reagent. Reactivity increases with the number of alkyl substituents.¹⁶³ Terminal alkenes are relatively inert. The reaction has a low ΔH^\ddagger and relative reactivity is dominated by entropic factors.¹⁶⁴ Steric effects govern the direction of approach of the oxygen, so the hydroperoxy group is usually introduced on the less hindered face of the double bond. A key mechanistic issue in singlet oxygen oxidations is whether it is a concerted process or involves an intermediate formulated as a “perepoxyde.” Most of the available evidence points to the perepoxyde mechanism.¹⁶⁵

Many alkenes present several different allylic hydrogens, and in this type of situation it is important to be able to predict the degree of selectivity.¹⁶⁶ A useful generalization is that *there is a preference for removal of a hydrogen from the more congested side of the double bond*.¹⁶⁷

This “*cis* effect” is ascribed to a more favorable TS when the singlet O_2 can interact with two allylic hydrogens. The stabilizing interaction has been described both in FMO¹⁶⁸ and hydrogen-bonding¹⁶⁹ terminology and can be considered an electrostatic effect. The *cis* effect does not apply to alkene having *t*-butyl substituents.¹⁷⁰ There are

probably two reasons for this: the *t*-butyl group does not provide any allylic hydrogens and its steric bulk may interfere with approach by $^1\text{O}_2$.

Polar functional groups such as carbonyl, cyano, and sulfoxide, as well as silyl and stannyl groups, exert a strong directing effect, favoring proton removal from the geminal methyl group.¹⁷¹

Hydroxy¹⁷² and amino¹⁷³ groups favor *syn* stereoselectivity. This is similar to the substituent effects observed for peroxy acids and suggests that the substituents may stabilize the TS by hydrogen bonding.

Recently techniques have been developed for $^1\text{O}_2$ oxidations in zeolite cavities.¹⁷⁴ The photosensitizer is absorbed in the zeolite and generation of $^1\text{O}_2$ and reaction with the alkene occurs within the cavity. The reactions under these conditions show changes in both regiochemistry¹⁷⁵ and stereoselectivity. The *cis* effect is reduced and there is a preference for hydrogen abstraction from methyl groups.

These changes in regio- and stereochemistry are likely due to conformation changes and electrostatic factors within the cavity. The intrazeolite oxidations can be improved by use of fluorocarbon solvents, owing to an enhanced lifetime of $^1\text{O}_2$ and to improved occupancy of the cavity by hydrocarbons in this solvent.¹⁷⁶

The singlet oxidation mechanism has been subject of a comparative study by kinetic isotope effects and computation of the reaction energy surface.¹⁷⁷ The reaction is described as proceeding through the perepoxide structure, but rather than being a distinct intermediate, this structure occurs at a saddle point on the energy surface; that is, there is no barrier to the second stage of the reaction, the hydrogen abstraction. Figure 12.12 is a representation of such a surface and Figure 12.13 shows the computed geometric characteristics for the perepoxides from *Z*-2-butene and 2,3-dimethyl-2-butene. This study also gives a consistent account for the *cis* effect. The perepoxide structure for engagement of the *cis* hydrogens is of lower energy than the corresponding structure involving the *trans* hydrogens. The *cis* transition structure is attained earlier and retains the synchronous character of the TSs from the symmetrical alkenes, as shown in Figure 12.14.

Scheme 12.17 gives some examples of oxidations by singlet oxygen. The reaction in Entry 1 was used to demonstrate that $^1\text{O}_2$ can be generated from H_2O_2 and ClO^- . Similarly, the reaction in Entry 2 was used to verify that the phosphite-ozone adducts

can serve as a $^1\text{O}_2$ source. The reactions in Entries 3 and 4 are representative photosensitized procedures with subsequent reduction of the hydroperoxide. Entry 5 used tetra-(perfluorophenyl)phorphyrin as the photosensitizer. This compound, as well as the tetra-(2,6-dichlorophenyl) analog, is reported to have improved stability to degradation under the reaction conditions. In this case the intermediate hydroperoxide was dehydrated to an enone using acetic anhydride. This reaction was carried out on a 25-g scale.

Certain compounds react with singlet oxygen in a different manner, giving dioxetanes as products.¹⁷⁸

This reaction is not usually a major factor with alkenes bearing only alkyl groups, but is important for vinyl ethers and other alkenes with donor substituents. These

12.3.3. Other Oxidants

Selenium dioxide is a useful reagent for allylic oxidation of alkenes. The products can include enones, allylic alcohols, or allylic esters, depending on the reaction conditions. The mechanism consists of three essential steps: (a) an electrophilic “ene” reaction with SeO_2 , (b) a [2,3]-sigmatropic rearrangement that restores the original location of the double bond, and (c) solvolysis of the resulting selenium ester.¹⁸³

The allylic alcohols that are the initial oxidation products can be further oxidized to carbonyl groups by SeO_2 and the conjugated carbonyl compound is usually isolated. If the alcohol is the desired product, the oxidation can be run in acetic acid, in which case acetate esters are formed.

The mechanism of the reaction has been studied by determining isotope effects for 2-methyl-2-butene and comparing them with predicted values.¹⁸⁴ The isotope effect at the vinyl hydrogen is 0.92 ± 0.01 , which is consistent with rehybridization. B3LYP/6-31G* computations located several related TSs with E_a values in the range of 6.0–8.9 kcal/mol. These TSs give calculated isotope effects in good agreement with the experimental values. Although these results are not absolutely definitive, they are consistent with the other evidence for a concerted ene-type mechanism as the first step in SeO_2 oxidation.

¹⁸⁴ D. A. Singleton and C. Hang, *J. Org. Chem.*, **65**, 7554 (2000).

Although the traditional conditions for effecting SeO_2 oxidations involve use of a stoichiometric or excess amount of SeO_2 , it is also possible to carry out the reaction with 1.5–2 mol % SeO_2 , using *t*-butyl hydroperoxide as a stoichiometric oxidant. Under these conditions, the allylic alcohol is the major product and is obtained in good yields, even from alkenes that are poorly reactive under the traditional conditions.¹⁸⁵

Trisubstituted alkenes are oxidized selectively at the more-substituted end of the carbon-carbon double bond, indicating that the ene reaction step is electrophilic in character.

Ref. 186

Selenium dioxide reveals a useful stereoselectivity when applied to trisubstituted *gem*-dimethyl alkenes. The products are predominantly the *E*-allylic alcohol or unsaturated aldehyde.¹⁸⁷

This stereoselectivity can be explained by a five-membered TS for the sigmatropic rearrangement step. The observed *E*-stereochemistry results if the larger alkyl substituent adopts a pseudoequatorial conformation.

The equivalent to allylic oxidation of alkenes, but with allylic transposition of the carbon-carbon double bond, can be carried out by an indirect oxidative process involving addition of an electrophilic arylselenenyl reagent, followed by oxidative elimination of selenium. In one procedure, addition of an arylselenenyl halide is followed by solvolysis and oxidative elimination.

Ref. 188

This reaction depends upon the facile solvolysis of β -haloselenides and the facile oxidative elimination of a selenoxide, which was discussed in Section 6.6.3. An alternative method, which is experimentally simpler, involves reaction of alkenes with a mixture of diphenyl diselenide and phenylseleninic acid.¹⁸⁹ The two selenium reagents generate an electrophilic selenium species, phenylselenenic acid, PhSeOH .

The elimination is promoted by oxidation of the addition product to the selenoxide by *t*-butyl hydroperoxide. The regioselectivity in this reaction is such that the hydroxy group becomes bound at the more-substituted end of the carbon-carbon double bond. The regioselectivity of the addition step follows Markovnikov's rule with PhSe^+ acting as the electrophile. The elimination step specifically proceeds away from the oxygen functionality.

12.4. Oxidative Cleavage of Carbon-Carbon Double Bonds

12.4.1. Transition Metal Oxidants

The most selective methods for cleaving organic molecules at carbon-carbon double bonds involve glycols as intermediates. Oxidations of alkenes to glycols was discussed in Section 12.2.1. Cleavage of alkenes can be carried out in one operation under mild conditions by using a solution containing periodate ion and a catalytic

¹⁸⁸. K. B. Sharpless and R. F. Lauer, *J. Org. Chem.*, **39**, 429 (1974); D. L. J. Clive, *J. Chem. Soc., Chem. Commun.*, 100 (1974).

¹⁸⁹. T. Hori and K. B. Sharpless, *J. Org. Chem.*, **43**, 1689 (1978).

amount of permanganate ion.¹⁹⁰ The permanganate ion effects the hydroxylation and the glycol is then cleaved by reaction with periodate. A cyclic intermediate is believed to be involved in the periodate oxidation. Permanganate is regenerated by the oxidizing action of periodate.

Osmium tetroxide used in combination with sodium periodate can also effect alkene cleavage.¹⁹¹ Successful oxidative cleavage of double bonds using ruthenium tetroxide and sodium periodate has also been reported.¹⁹² In these procedures the osmium or ruthenium can be used in substoichiometric amounts because the periodate reoxidizes the metal to the tetroxide state. Entries 1 to 4 in Scheme 12.18 are examples of these procedures. Entries 5 and 6 show reactions carried out in the course of multistep syntheses. The reaction in Entry 5 followed a 5-*exo* radical cyclization and served to excise an extraneous carbon. The reaction in Entry 6 followed introduction of the allyl group by enolate alkylation. The aldehyde group in the product was used to introduce an amino group by reductive alkylation (see Section 5.3.1.2).

The strong oxidants Cr(VI) and MnO_4^- can also be used for oxidative cleavage of double bonds, provided there are no other sensitive groups in the molecule. The permanganate oxidation proceeds first to the diols and ketols, as described earlier (see p. 1075), and these are then oxidized to carboxylic acids or ketones. Good yields can be obtained provided care is taken to prevent subsequent oxidative degradation of the products. The oxidation of cyclic alkenes by Cr(VI) reagents can be a useful method for formation of dicarboxylic acids. The initial oxidation step appears to yield an epoxide that undergoes solvolytic ring opening to a glycol or glycol monoester, which is then oxidatively cleaved.¹⁹³ Two possible complications that can be encountered are competing allylic attack and skeletal rearrangement. Allylic attack can lead to eventual formation of a dicarboxylic acid that has lost one carbon atom. Pinacol-type rearrangements of the epoxide or glycol intermediates can give rise to rearranged products.

Entries 7 to 9 in Scheme 12.18 are illustrative of these oxidative ring cleavages.

The reaction of alkenes with ozone is a general and selective method of cleaving carbon-carbon double bonds.¹⁹⁴ Application of low-temperature spectroscopic techniques has provided information about the rather unstable intermediates in the ozonolysis process. These studies, along with isotopic-labeling results, have provided an understanding of the reaction mechanism.¹⁹⁵ The two key intermediates in ozonolysis are the 1,2,3-trioxolane, or initial ozonide, and the 1,2,4-trioxolane, or ozonide. The first step of the reaction is a 1,3-dipolar cycloaddition to give the 1,2,3-trioxolane. This is followed by a fragmentation and recombination to give the isomeric 1,2,4-trioxolane. Ozone is a very electrophilic 1,3-dipole because of the accumulation of electronegative oxygen atoms in the ozone molecule. The cycloaddition, fragmentation, and recombination are all predicted to be exothermic on the basis of thermochemical considerations.¹⁹⁶

The products isolated after ozonolysis depend upon the conditions of workup. Simple hydrolysis leads to the carbonyl compounds and hydrogen peroxide, and these can react to give secondary oxidation products. It is usually preferable to include a mild reducing agent that is capable of reducing peroxidic bonds. The current practice is to use dimethyl sulfide, though numerous other reducing agents have been used, including zinc,¹⁹⁷ trivalent phosphorus compounds,¹⁹⁸ and sodium sulfite.¹⁹⁹ If the alcohols resulting from the reduction of the carbonyl cleavage products are desired, the reaction mixture can be reduced with NaBH_4 .²⁰⁰ Carboxylic acids are formed in good yields from aldehydes when the ozonolysis reaction mixture is worked up in the presence of excess hydrogen peroxide.²⁰¹

Several procedures that intercept the intermediates have been developed. When ozonolysis is done in alcoholic solvents, the carbonyl oxide fragmentation product can be trapped as an α -hydroperoxy ether.²⁰² Recombination to the ozonide is then prevented, and the carbonyl compound formed in the fragmentation step can also be

isolated. If the reaction mixture is then treated with dimethyl sulfide, the hydroperoxide is reduced and the second carbonyl compound is also formed in good yield.²⁰³

Ozonolysis in the presence of NaOH or NaOCH₃ in methanol with CH₂Cl₂ as a cosolvent leads to formation of esters. This transformation proceeds by trapping both

²⁰³ J. J. Pappas, W. P. Keaveney, E. Gancher, and M. Berger, *Tetrahedron Lett.*, 4273 (1966).

the carbonyl oxide and aldehyde products of the fragmentation step.²⁰⁴ The anionic adducts are then oxidized by O_3 .

Cyclooctene gives dimethyl octanedioate under these conditions.

Especially reactive carbonyl compounds such as methyl pyruvate can trap the carbonyl oxide component. For example, ozonolysis of cyclooctene in the presence of methyl pyruvate leads to **5**; when treated with triethylamine **5** is converted to **6**, in which the two carbons of the original double bond have been converted to different functionalities.²⁰⁵

Scheme 12.19 illustrates some cases in which ozonolysis reactions have been used in the course of syntheses. Entries 1 to 4 are examples of use of ozonolysis to introduce carbonyl groups under reductive workup. Entries 5 and 6 involve oxidative workup and give dicarboxylic acid products. The reaction in Entry 7 is an example of direct generation of a methyl ester by methoxide trapping.

12.5. Oxidation of Ketones and Aldehydes

12.5.1. Transition Metal Oxidants

Ketones are oxidatively cleaved by Cr(VI) or Mn(VII) reagents. The reaction is sometimes of utility in the synthesis of difunctional molecules by ring cleavage. The mechanism for both reagents is believed to involve an enol intermediate.²⁰⁶ A study involving both kinetic data and quantitative product studies has permitted a fairly complete description of the Cr(VI) oxidation of benzyl phenyl ketone.²⁰⁷ The products include both oxidative-cleavage products and benzil, **7**, which results from oxidation α to the carbonyl. In addition, the dimeric product **8**, which is suggestive of radical intermediates, is formed under some conditions.

Both the diketone and the cleavage products were shown to arise from an α -hydroxyketone intermediate (benzoin) **9**.

The coupling product is considered to involve a radical intermediate formed by one-electron oxidation, probably effected by Cr(IV). Similarly, the oxidation of cyclohexanone involves 2-hydroxycyclohexanone and 1,2-cyclohexanedione as intermediates.²⁰⁸

Owing to the efficient oxidation of alcohols to ketones, alcohols can be used as the starting materials in oxidative cleavages. The conditions required are more vigorous than for the alcohol to ketone transformation (see Section 12.1.1).

Aldehydes can be oxidized to carboxylic acids by both Mn(VII) and Cr(VI). Fairly detailed mechanistic studies have been carried out for Cr(VI). A chromate ester of the aldehyde hydrate is believed to be formed, and this species decomposes in the rate-determining step by a mechanism similar to the one that operates in alcohol oxidations.²⁰⁹

Effective conditions for oxidation of aldehydes to carboxylic acids with KMnO_4 involve use of *t*-butanol and an aqueous NaH_2PO_4 buffer as the reaction medium.²¹⁰ Buffered sodium chlorite is also a convenient oxidant.²¹¹ Both KMnO_4 and NaClO_2 can be used in the form of solid-supported materials, using silica and ion exchange resins, respectively,²¹² which permits facile workup of the product. Silver oxide is one of the older reagents used for carrying out the aldehyde to carboxylic acid oxidation.

The reaction of aldehydes with MnO_2 in the presence of cyanide ion in an alcoholic solvent is a convenient method of converting aldehydes directly to esters.²¹⁴ This reaction involves the cyanohydrin as an intermediate. The initial oxidation product is an acyl cyanide, which is solvolyzed under these reaction conditions.

Lead tetraacetate can effect oxidation of carbonyl groups, leading to formation of α -acetoxy ketones,²¹⁵ but the yields are seldom high. Boron trifluoride can be used to catalyze these oxidations. It is presumed to function by catalyzing the formation of the enol, which is thought to be the reactive species.²¹⁶ With unsymmetrical ketones, products from oxidation at both α -methylene groups are found.²¹⁷

With enol ethers, $\text{Pb}(\text{OCCH}_3)_4$ gives α -methoxyketones.²¹⁸

Introduction of oxygen α to a ketone function can also be carried out via the silyl enol ether. Lead tetraacetate gives the α -acetoxy ketone.²¹⁹

α -Hydroxyketones can be obtained from silyl enol ethers by oxidation using a catalytic amount of OsO_4 with an amine oxide serving as the stoichiometric oxidant.²²⁰

Ref. 221

Other procedures for α -oxidation of ketones are based on prior generation of the enolate. Among the reagents used is a molybdenum compound, MoO_5 -pyridine-HMPA, which is prepared by dissolving MoO_3 in hydrogen peroxide, followed by addition of HMPA. This reagent oxidizes the enolates of aldehydes, ketones, esters, and lactones to the corresponding α -hydroxy compound.²²²

Ref. 223

12.5.2. Oxidation of Ketones and Aldehydes by Oxygen and Peroxidic Compounds

12.5.2.1. Baeyer-Villiger Oxidation of Ketones. In the presence of acid catalysts, peroxy compounds are capable of oxidizing ketones by insertion of an oxygen atom into one of the carbon-carbon bonds at the carbonyl group. Known as the *Baeyer-Villiger oxidation*,²²⁴ the mechanism involves a sequence of steps that begins with addition to the carbonyl group, followed by peroxide bond cleavage with migration to oxygen.

The concerted O–O heterolysis-migration is usually the rate-determining step.²²⁵ The reaction is catalyzed by protic and Lewis acids,²²⁶ including $\text{Sc}(\text{O}_3\text{SCF}_3)_3$ ²²⁷ and $\text{Bi}(\text{O}_3\text{SCF}_3)_3$.²²⁸

When the reaction involves an unsymmetrical ketone, the structure of the product depends on which group migrates. A number of studies have been directed at ascertaining the basis of migratory preference in the Baeyer-Villiger oxidation, and a general order of likelihood of migration has been established: *tert*-alkyl, *sec*-alkyl > benzyl, phenyl > *pri*-alkyl > cyclopropyl > methyl.²²⁹ Thus, methyl ketones uniformly give acetate esters resulting from migration of the larger group.²³⁰ A major factor in determining which group migrates is the ability to accommodate partial positive charge. In *para*-substituted phenyl groups, ERG substituents favor migration.²³¹ Similarly, silyl substituents enhance migratory aptitude of alkyl groups.²³² As is generally true of migration to an electron-deficient center, the configuration of the migrating group is retained in Baeyer-Villiger oxidations.

Steric and conformational factors are also important, especially in cyclic systems.²³³ There is a preference for the migration of the group that is antiperiplanar with respect to the peroxide bond. In relatively rigid systems, this effect can outweigh the normal preference for the migration of the more branched group.²³⁴

This stereoelectronic effect also explains the contrasting regioselectivity of *cis*- and *trans*-2-fluoro-4-*t*-butylcyclohexanone.²³⁵ As a result of a balance between its polar effect and hyperconjugation, the net effect of a fluoro substituent in acyclic systems is small. However, in 2-fluorocyclohexanones an unfavorable dipole-dipole interaction comes into play for the *cis* isomer and preferential migration of the fluoro-substituted carbon is observed.

In 2-(trifluoromethyl)cyclohexanone, the methylene group migrates in preference to the trifluoromethylmethine group,²³⁶ owing primarily to the EWG effect of the trifluoromethyl group. The computational energy profile, shown in Figure 12.15, indicates that the reaction proceeds through a minor conformation of the adduct in which the trifluoromethyl group is axial. The same regioselectivity is computed for the adduct having the peroxy substituent in an equatorial position, but this adduct is about 1 kcal/mol higher in energy.

The Baeyer-Villiger reaction has found considerable application in the synthesis of prostaglandins. One common pattern involves the use of bicyclo[2.2.1]heptan-2-one derivatives, which are generally obtained by Diels-Alder reactions. For example, compound **10** is known as the *Corey lactone* and has played a prominent role in the synthesis of prostaglandins.²³⁷ This compound was originally prepared by a Baeyer-Villiger oxidation of 7-(methoxymethyl)bicyclo[2.2.1]hept-5-en-2-one.²³⁸

This intermediate has the oxygenation and pattern and *trans*-disubstitution pattern found in the prostaglandins. Several syntheses of similar intermediates have been developed.²³⁹

In the synthesis of Travoprost, an antiglaucoma agent, a bicyclo[2.2.1]heptan-2-one is converted to a lactone.²⁴⁰ The commercial process uses peroxyacetic acid as the oxidant and gives a 40% yield. The regioselectivity in this case is only 3:1 but the unwanted isomer can be removed by selective hydrolysis.

A series of 2-vinyl-3-silyloxybicyclo[3.2.0]heptan-6-ones has also been converted to prostanoid lactones in excellent yield but variable regioselectivity. Some of the best regioselectivity was obtained using H_2O_2 in trifluoroethanol (see p. 1097).²⁴¹ The strained cyclobutanone ring and the relatively unreactive terminal vinyl group favor the desired reaction in preference to alkene epoxidation.

Some typical examples of Baeyer-Villiger oxidations are shown in Scheme 12.20. Entry 1 uses peroxysulfuric acid, the original reagent discovered by Baeyer and Villiger. Entries 2 and 3 generate lactones in good yield from cyclic ketones using peroxyacetic acid. Entry 3 also illustrates the preference for the migration of the more branched group. Entry 4 is a case of formation of an acetate ester from a methyl ketone. Entry 5 illustrates the use of magnesium monoperoxyphthalate and also shows the normal preference for migration of the more branched group. The reaction in Entry 6 exhibits very high regioselectivity. Although this example is consistent with the generalization that the more branched group will migrate, there may be other factors associated with ring geometry that lead to the complete regioselectivity. Entries 7 and 8 use peroxytrifluoroacetic acid and again illustrate the conversion of methyl ketones to acetate esters.

12.5.2.2. Oxidation of Enolates and Enolate Equivalents. Although ketones are essentially inert to molecular oxygen, enolate anions are susceptible to oxidation. The combination of oxygen and a strong base has found some utility in the introduction of an oxygen function at carbanionic sites.²⁴² Hydroperoxides are the initial products of such oxidations, but when DMSO or some other substance capable of reducing the hydroperoxide is present, the corresponding alcohol is isolated. A procedure that has met with

considerable success involves oxidation in the presence of a trialkyl phosphite.²⁴³ The intermediate hydroperoxide is efficiently reduced by the phosphite ester.

This oxidative process has been successful with ketones,²⁴⁴ esters,²⁴⁵ and lactones.²⁴⁶ Hydrogen peroxide can also be used as the oxidant, in which case the alcohol is formed directly.²⁴⁷ The mechanisms for the oxidation of enolates by oxygen is a radical chain autoxidation in which the propagation step involves electron transfer from the carbanion to a hydroperoxy radical.²⁴⁸

Arguments for a nonchain reaction between the enolate and oxygen to give the hydroperoxide anion directly have been advanced as well.²⁴⁹

The silyl enol ethers of ketones are also oxidized to α -hydroxy ketones by *m*-chloroperoxybenzoic acid. If the reaction workup includes acylation, α -acyloxy ketones are obtained.²⁵⁰ These reactions proceed by initial epoxidation of the silyl enol ether, which then undergoes ring opening. Subsequent transfer of either the *O*-acyl or *O*-TMS substituent occurs, depending on the reaction conditions.

N-Sulfonyloxaziridines are useful reagents for oxidation of enolates to α -hydroxyketones.²⁵¹ The best results are frequently achieved by using KHMDS to form the enolate. The hydroxylation occurs preferentially from the less hindered enolate face.

The mechanism of oxygen transfer is believed to involve nucleophilic opening of the oxaziridine, followed by collapse of the resulting *N*-sulfonylcarbinolamine.²⁵²

These reagents exhibit good stereoselectivity toward chiral reactants, such as acyloxazolidinones.²⁵³ Chiral oxaziridine reagents have been developed that can achieve enantioselective oxidation of enolates to α -hydroxyketones.²⁵⁴

Scheme 12.21 gives some examples of enolate oxidation using *N*-sulfonyloxaziridines. Entries 1 to 3 are examples of enantioselective oxidations using chiral oxaziridines with racemic reactants. In Entry 4, the stereoselectivity is presumably controlled by the reactant shape. The analog with all *cis* stereochemistry at the cyclobutane ring also gave oxidation from the less hindered face of the molecule. Entry 5 is an example of diastereoselective oxidation. The observed *syn* selectivity is consistent with reactant conformation being the controlling factor in reagent approach.

Both the regio- and stereochemistry of Entry 6 are of interest. The regioselectivity is imposed by the rigid ring geometry, which favors enolization at the observed position. Inspection of a molecular model also shows that α -face of the enolate is more accessible.

Selenium dioxide can be used to oxidize ketones and aldehydes to α -dicarbonyl compounds. The reaction often gives high yields of products when there is a single type of CH_2 group adjacent to the carbonyl group. In unsymmetrical ketones, oxidation usually occurs at the CH_2 that is most readily enolized.²⁵⁵

The oxidation is regarded as taking place by an electrophilic attack of selenium dioxide (or selenous acid, H_2SeO_3 , the hydrate) on the enol of the ketone or aldehyde. This is followed by hydrolytic elimination of the selenium.²⁵⁸

Methyl ketones are degraded to the next lower carboxylic acid by reaction with hypochlorite or hypobromite ions. The initial step in these reactions involves base-catalyzed halogenation. The α -haloketones are more reactive than their precursors, and rapid halogenation to the trihalo compound results. Trihalomethyl ketones are susceptible to alkaline cleavage because of the inductive stabilization provided by the halogen atoms.

12.6. Selective Oxidative Cleavages at Functional Groups

12.6.1. Cleavage of Glycols

As discussed in connection with cleavage of double bonds by permanganate-periodate or osmium tetroxide-periodate (see p. 1127), the glycol unit is susceptible to mild oxidative cleavage. The most commonly used reagent for this oxidative cleavage is the periodate ion.²⁶¹ The fragmentation is believed to occur via a cyclic adduct of the glycol and the oxidant.

Structural features that retard formation of the cyclic intermediate decrease the reaction rate. For example, *cis*-1,2-dihydroxycyclohexane is substantially more reactive than the *trans* isomer.²⁶² Glycols in which the geometry of the molecule precludes the possibility of a cyclic intermediate are essentially inert to periodate.

Certain other combinations of adjacent functional groups are also cleaved by periodate. Diketones are cleaved to carboxylic acids, and it is proposed that a reactive cyclic intermediate is formed by nucleophilic attack on the diketone.²⁶³

α -Hydroxy ketones and α -amino alcohols are also subject to oxidative cleavage, presumably by a similar mechanism.

Lead tetraacetate is an alternative reagent to periodate for glycol cleavage. It is particularly useful for glycols that have low solubility in the aqueous media used for periodate reactions. A cyclic intermediate is suggested by the same kind of stereochemistry-reactivity relationship discussed for periodate.²⁶⁴ Unlike periodate, however, glycols that cannot form cyclic intermediates are eventually oxidized. For example, *trans*-9,10-dihydroxydecalin is oxidized, but the rate is 100 times less than for the *cis* isomer.²⁶⁵ Thus, whereas a cyclic mechanism appears to provide the lowest-energy pathway for this oxidative cleavage, it is not the only possible mechanism. Both

the periodate cleavage and lead tetraacetate oxidation can be applied synthetically to the generation of medium-sized rings when the glycol is at the junction of two rings.

Ref. 266

12.6.2. Oxidative Decarboxylation

Carboxylic acids are oxidized by lead tetraacetate. Decarboxylation occurs and the product may be an alkene, alkane or acetate ester, or under modified conditions a halide. A free radical mechanism operates and the product composition depends on the fate of the radical intermediate.²⁶⁷ The reaction is catalyzed by cupric salts, which function by oxidizing the intermediate radical to a carbocation (Step 3b in the mechanism). Cu(II) is more reactive than Pb(OAc)₄ in this step.

Alkanes are formed when the radical intermediate abstracts hydrogen from solvent faster than it is oxidized to the carbocation. This reductive step is promoted by good hydrogen donor solvents. It is also more prevalent for primary alkyl radicals because of the higher activation energy associated with formation of primary carbocations. The most favorable conditions for alkane formation involve photochemical decomposition of the carboxylic acid in chloroform, which is a relatively good hydrogen donor.

Ref. 268

Normally, the dominant products are the alkene and acetate ester, which arise from the carbocation intermediate by, respectively, elimination of a proton and capture of an acetate ion.²⁶⁹

Oxidation of β -silyl and β -stannyl acids leads to loss of the substituent and alkene formation.²⁸³

12.7. Oxidations at Unfunctionalized Carbon

Attempts to achieve selective oxidations of hydrocarbons or other compounds when the desired site of attack is remote from an activating functional group are faced with several difficulties. With powerful transition-metal oxidants, the initial oxidation products are almost always more susceptible to oxidation than the starting material. When a hydrocarbon is oxidized, it is likely to be oxidized to a carboxylic acid, with chain cleavage by successive oxidation of alcohol and carbonyl intermediates. There are a few circumstances under which oxidations of hydrocarbons can be synthetically useful processes. One group involves catalytic industrial processes. Much effort has been expended on the development of selective catalytic oxidation processes and several have economic importance. We focus on several reactions that are used on a laboratory scale.

The most general hydrocarbon oxidation is the oxidation of side chains on aromatic rings. Two factors contribute to making this a high-yield procedure, despite the use of strong oxidants. First, the benzylic position is susceptible to hydrogen abstraction by the oxidants.²⁸⁴ Second, the aromatic ring is resistant to attack by Mn(VII) and Cr(VI) reagents that oxidize the side chain.

Scheme 12.22 provides some examples of the oxidation of aromatic alkyl substituents to carboxylic acid groups. Entries 1 to 3 are typical oxidations of aromatic methyl groups to carboxylic acids. Entries 4 and 5 bring the carbon adjacent to the aromatic ring to the carbonyl oxidation level.

Selective oxidations are possible for certain bicyclic hydrocarbons.²⁸⁵ Here, the bridgehead position is the preferred site of initial attack because of the order of reactivity of C—H bonds, which is $3^\circ > 2^\circ > 1^\circ$. The tertiary alcohols that are the initial oxidation products are not easily further oxidized. The geometry of the bicyclic rings (*Bredt's rule*) prevents both dehydration of the tertiary bridgehead alcohols and further oxidation to ketones. Therefore, oxidation that begins at a bridgehead position

stops at the alcohol stage. Chromic acid oxidation has been the most useful reagent for functionalizing unstrained bicyclic hydrocarbons. The reaction fails for strained bicyclic compounds such as norbornane because the reactivity of the bridgehead position is lowered by the unfavorable energy of radical or carbocation intermediates.

Other successful selective oxidations of hydrocarbons by Cr(VI) have been reported—for example, the oxidation of *cis*-decalin to the corresponding alcohol—but careful attention to reaction conditions is required.

(References for these problems will be found on page 1290.)

12.1. Indicate an appropriate oxidant for carrying out the following transformations.

12.2. Predict the products of the following reactions. Be careful to consider all stereochemical aspects.

- 12.3. In chromic acid oxidation of stereoisomeric cyclohexanols, it is usually found that axial hydroxy groups react more rapidly than equatorial groups. For example, *trans*-4-*t*-butylcyclohexanol is less reactive (by a factor of 3.2) than the *cis* isomer. An even larger difference is noted with *cis*- and *trans*-3,3,5-trimethylcyclohexanol. The axial hydroxy in the *trans* isomer is 35 times more reactive than the equatorial hydroxy in the *cis* isomer, even though it is in a more hindered environment. A general relationship is found for pairs of epimeric cyclohexanols in that the ratio of the rates of the isomers is approximately equal to the equilibrium constant for equilibration of the isomers: $k_{ax}/k_{eq} \sim K_{ax/eq}$. Are these data compatible with the mechanism given on p. 1064? What additional details do these data provide about the reaction mechanism? Explain.
- 12.4. Predict the products from opening of the two stereoisomeric epoxides derived from limonene shown below by reaction with (a) acetic acid and (b) dimethylamine.

- 12.5. The direct oxidative conversion of primary halides and sulfonates to aldehydes can be carried out by reaction with DMSO under alkaline conditions. Formulate a mechanism for this reaction.

12.6. The following questions pertain to the details of mechanism of ozonolysis under modified conditions.

- a. A method for synthesis of ozonides that involves no ozone has been reported. It consists of photosensitized oxidation of diazo compounds in the presence of an aldehyde. Suggest a mechanism for this reaction.

- b. Overoxidation of carbonyl products during ozonolysis can be prevented by addition of tetracyanoethylene to the reaction mixture. The stoichiometry of the reaction is then:

Propose a mechanism that would account for the effect of tetracyanoethylene. Does your mechanism suggest that tetracyanoethylene would be a particularly effective alkene for this purpose? Explain.

- c. It has been found that when unsymmetrical alkenes are ozonized in methanol, there is often a large preference for one cleavage mode of the initial ozonide over the other. For example:

Account for this selectivity.

12.7. Suggest mechanisms by which the “abnormal” oxidations shown below could occur.

12.8. Indicate one or more satisfactory oxidants for effecting the following transformations. Each molecule poses issues of selectivity or the need to preserve a sensitive functional group. Select oxidants that can avoid the installation of protecting groups. In most cases, a one-pot reaction is possible, and in no case is a sequence of more than three steps required. Explain the reason for your choice of reagent(s).

- 12.9. A method for oxidative cleavage of cyclic ketones involves a four-stage process. First, the ketone is converted to an α -phenylthio derivative (see Section 4.3.2). The ketone is then converted to an alcohol, either by reduction with NaBH_4 or by addition of an organolithium reagent. The alcohol is then treated with $\text{Pb}(\text{OAc})_4$ to give an oxidation product in which the hydroxy group has been acetylated and an additional oxygen added to the β -thioalcohol. Aqueous hydrolysis of this intermediate in the presence of Hg^{2+} gives a dicarbonyl compound. Formulate likely structures for the products of each step in this sequence.

- 12.10. The transformations shown below have been carried out using reaction sequences involving several oxidation steps. Devise a series of steps that could accomplish these transformations and suggest reagents that would be suitable for each step. Some sequences may also require nonoxidative steps, such as introduction or removal of protecting groups.

- 12.11. Provide mechanistic interpretations of the following reactions.

- a. Account for the products formed under the following conditions. In particular, why does the inclusion of cupric acetate change the course of the reaction?

b. Account for this oxidative decyanation.

c. It is found that the oxidative decarboxylation of β -silyl and β -stannyl carboxylic acids is substantially accelerated by cupric acetate.

12.12. Use retrosynthetic analysis to devise a sequence of reactions that could accomplish the formation of the structure on the left from the potential precursor on the right.

- 12.13. Tomoxetine and fluoxetine are antidepressants. Both enantiomers of each compound can be prepared enantiospecifically starting from cinnamyl alcohol. Give a reaction sequence that will accomplish this objective.

- 12.14. The irradiation of **14-A** in the presence of rose bengal and oxygen in methanol gives **14-B** as the only observable product (72% yield). When the irradiation is carried out in acetaldehyde as solvent, the yield of **14-B** is reduced to 54% and two additional products, **14-C** (19%) and **14-D** (17%), are formed. Account for the formation of each product.

- 12.15. Analyze the following data on the product ratios obtained in the epoxidation of 3-substituted cyclohexenes by dimethyldioxirane. What are the principal factors that determine the stereoselectivity?

Substituent	<i>trans</i> : <i>cis</i> ^a
OH	66:34 ^b
OH	15:85
OCH ₃	85:15
O ₂ CCH ₃	62:38
CO ₂ CH ₃	68:32
CO ₂ H	84:16

(Continued)

Substituent	<i>trans:cis</i> ^a
NHCOPh	3:97
Cl	90:10 ^c
CF ₃	90:10 ^c
CH ₃	47:53
(CH ₃) ₂ CHCH ₂	54:46
(CH ₃) ₃ C	95:5 ^c
Ph	85:15

a. Solvent is 9:1 CCl₄-acetone except as noted otherwise.

b. Solvent is 9:1 methanol-acetone.

c. Solvent is acetone.

12.16. Offer a mechanistic explanation for the following observations.

- a. A change from ether as solvent to pentane with 12-crown-4 reverses the stereoselectivity of LiAlH₄ reduction of *cis*-3-benzyloxycyclohexene oxide, but not the *trans* isomer.

			
			
LiAlH ₄ -ether	2	98	97
LiAlH ₄ -pentane 12-crown-4	82	18	97
			3

- b. In the presence of a strong protic acid or a Lewis acid, acetophenones and propiophenones rearrange to arylalkanoic acid on reaction with Pb(OAc)₄.

- c. Acylation leads to reaction of the hydroperoxides **16α** and **16β**, but the products are different. In **16β**, the vinyl substituent migrates giving ring expansion, whereas with **16α** an enone is formed.

- 12.17. Various terpene-derived materials are important in the formulation of fragrances and flavors. One example is the tricyclic furan shown below, which is commercially used under the trademark Ambrox.[®] The synthetic sequences below have been developed to prepare related structures. Suggest reagents for each step in these sequences.

- a. This sequence was developed to avoid the use of transition metal reagents and minimize by-products.

- b. The following sequence led to the 6- α -hydroxy derivative.

- 12.18. The closely related enones **18-A** and **18-B** give different products when treated with $\text{Pb}(\text{OAc})_4$ in CH_3CN . Formulate mechanisms to account for both products and identify the factor(s) that lead to the divergent structures.

12.19. Predict the structure and stereochemistry of the Lewis acid-catalyzed rearrangement of the following epoxides.

Multistep Syntheses

Introduction

The reactions discussed in the preceding chapters provide tools for synthesizing new and complex molecules, but a strategy for using these reactions is essential for successful multistep syntheses. The sequence of individual reactions must be planned so that the reactions are mutually compatible with the final synthetic goal. Certain functional groups can interfere with prospective reactions and such problems must be avoided either by a modification of the sequence or by temporarily masking (protecting) the interfering group. *Protective groups* are used to temporarily modify functionality, which is then restored when the protecting group is removed. Another approach is to use a *synthetic equivalent group* in which a particular functionality is introduced as an alternative structure that can subsequently be converted to the desired group.

Protective groups and synthetic equivalent groups are tactical tools of multistep syntheses. They are the means, along with the individual synthetic methods, to reach the goal of a completed synthesis, and these tactical steps must be incorporated into an overall synthetic plan. A synthetic plan is normally created on the basis of a *retrosynthetic analysis*, which involves identification of the particular bonds that can be formed to obtain the desired molecule. Depending on the complexity of the synthetic target, the retrosynthetic analysis may be obvious or intricate. A synthetic plan identifies potential starting materials and reactions that can lead to the desired molecule, and most such plans involve a combination of *linear sequences* and *convergent steps*. Linear sequences construct the target molecule step-by-step by incremental additions and functional group transformations. Convergent steps bring together larger segments of the molecule that have been created by linear sequences. As the overall synthetic yield is the multiplication product of the yield of each of the individual steps in the synthesis, incorporation of a convergent step improves overall yield by reducing the length of the linear sequences. After discussing some general aspects of synthetic analysis and planning, we summarize several syntheses that illustrate application of multistep synthetic methods to representative molecules. In the final sections of the chapter, we consider solid phase synthesis and its application to polypeptide, polynucleotide, and combinatorial syntheses.

13.1. Synthetic Analysis and Planning

13.1.1. Retrosynthetic Analysis

The tools available to the synthetic chemist, consist of an extensive catalog of reactions and the associated information on such issues as stereoselectivity and mutual reactivity. This knowledge permits a judgment on the applicability of a particular reaction in a synthetic sequence. Broad mechanistic insight is also crucial to synthetic analysis. The relative position of functional groups in a potential reactant may lead to specific interactions or reactions. The ability to recognize such complications enables appropriate adjustments to the synthetic plan. Mechanistic concepts can guide optimization of reaction conditions. They are as well the basis for developing new reactions that may be necessary in a particular situation.

The planning of a synthesis involves a critical comparative evaluation of alternative reaction sequences that could reasonably be expected to lead to the desired structure from appropriate starting materials. In general, the complexity of a synthetic plan increases with the size of the molecule and with increasing numbers of functional groups and stereogenic centers. The goal of synthetic analysis is to recognize possible pathways to the target compound and to develop a suitable sequence of synthetic steps. In general, a large number of syntheses of any given compound are possible. The objective of synthetic analysis and planning is to develop a reaction sequence that will complete the desired synthesis efficiently within the constraints that apply.

The restrictions that apply depend on the purposes for which the synthesis is being done. A synthesis of a material to be prepared in substantial quantity may impose a limitation on the cost of the starting materials. Syntheses for commercial production must meet such criteria as economic feasibility, acceptability of by-products, and safety. Syntheses of structures having several stereogenic centers must deal with the problem of stereoselectivity. If an enantiomerically pure material is to be synthesized, the means of controlling absolute configuration must be considered. The development of a satisfactory plan is the chemist's intellectual challenge and it puts a premium on creativity and ingenuity. There is no single correct solution. Although there is no established routine by which a synthetic plan can be formulated, general principles that can guide synthetic analysis and planning have been described.¹

The initial step in creating a synthetic plan involves a *retrosynthetic analysis*. The structure of the molecule is dissected step by step along reasonable pathways to successively simpler compounds until molecules that are acceptable as starting materials are identified. Several factors enter into this process, and all are closely interrelated. The recognition of *bond disconnections* allows the molecule to be broken down into *key intermediates*. Such disconnections must be made in such a way that it is feasible to form the bonds by some synthetic process. The relative placement of potential functionality strongly influences which bond disconnections are preferred. To emphasize that these disconnections must correspond to transformations that can be conducted in the synthetic sense, they are sometimes called *antisynthetic transforms*, i.e., the reverse of synthetic steps. An open arrow symbol, \Rightarrow , is used to indicate an antisynthetic transform.

Retrosynthetic analysis can identify component segments of a target molecule that can serve as key intermediates, and the subunits that are assembled to construct

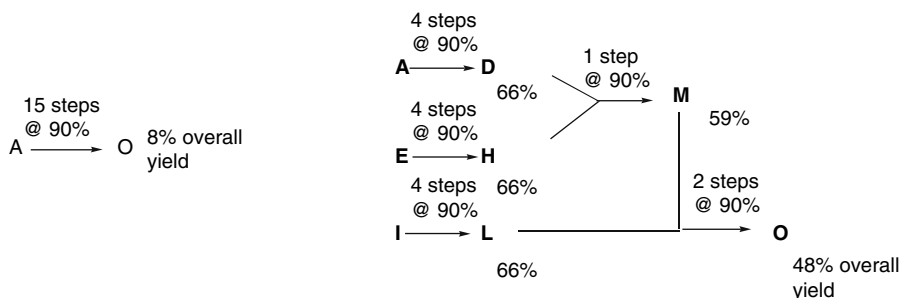

¹ E. J. Corey and X.-M. Cheng, *The Logic of Chemical Synthesis*, Wiley, New York, 1989.

them are sometimes called *synthons*. Synthons must not only correspond structurally to the desired subunit, but they must also have appropriate reactivity to allow bond formation with adjacent subunits. For example, in the case of aldol reactions, one reagent must serve as the electrophile and the other as the nucleophile. In a ring construction by a Diels-Alder reaction, the diene and dienophile must have compatible reactivity. Similarly, in bond constructions done using organometallic intermediates, the synthons must possess appropriate mutual reactivity.

The overall synthetic plan consists of a sequence of reactions designed to construct the total molecular framework from the key intermediates. The plan should take into account the advantages of a *convergent synthesis*. The purpose of making a synthesis more convergent is to shorten its overall length. In general, it is desirable to construct the molecule from a few key segments that can be combined late in the synthesis rather than build the molecule step-by-step from a single starting material. The overall yield is the multiplication product of the yields for all the individual steps. Overall yields decrease with the increasing number of steps to which the original starting material is subjected.² One of the characteristics of a multistep sequence is the *longest linear sequence*, which is the maximum number of steps from an original starting material to the final product. For example, in the case below, a single convergency that reduces the longest linear sequence from six to three improves the overall yield from 53% to 73% if the yield was 90% in each transformation.

Splitting a 15-step synthesis into three branches of four steps each will improve the yield from 8 to 48% if each step occurs in 90% yield.

After a plan for assembly of the key intermediates into the molecular framework has been developed, the details of incorporation and transformation of functional

². A formal analysis of the concept of convergency has been presented by J. B. Hendrickson, *J. Am. Chem. Soc.*, **99**, 5439 (1977).

groups are considered. It is frequently necessary to interconvert functional groups, which may be done to develop a particular kind of reactivity at a center or to avoid interference with a reaction step. Protective groups and synthetic equivalent groups are important for planning of functional group transformations. Owing to the large number of procedures for interconverting the common functional groups, achieving the final array of functionality is often less difficult than establishing the overall molecular skeleton and stereochemistry.

The synthetic plan must also provide for control of stereochemistry. In the case of cyclic compounds, advantage often can be taken of the facial preferences of the rings and the stereoselectivity of reagents to establish the stereochemistry of substituents. For example, the *syn*-directive effect of hydroxy groups in epoxidation (see p. 1093) or the strong preference for *anti* addition in iodolactonization (see p. 311) can be used to determine the configuration of new stereogenic centers. Similarly, the cyclic TS of sigmatropic rearrangements often allows predictable stereoselectivity. Chiral auxiliaries and catalysts provide means of establishing configuration in enantioselective syntheses. A plan for a stereo- or enantioselective synthesis must include the basis for controlling the configuration at each stereocenter.

The care with which a synthesis is analyzed and planned will have a great impact on the likelihood of its success. The investment of material and effort that is made when the synthesis is begun may be lost if the plan is faulty. Even with the best of planning, however, unexpected problems are often encountered. This circumstance again tests the ingenuity of the chemist to devise a modified plan that can overcome the unanticipated obstacle.

13.1.2. Synthetic Equivalent Groups

Retrosynthetic analysis may identify a need to use *synthetic equivalent groups*. These groups are synthons that correspond structurally to a subunit of the target structure, but in which the reactivity of the functionality is masked or modified. As an example, suppose the transformation shown below was to be accomplished.

The electrophilic α,β -unsaturated ketone is reactive toward nucleophiles, but the nucleophile that is required, an acyl anion, is not normally an accessible entity. There are several potential reagents that could introduce the desired acyl anion in a masked form. The masked functionality used in place of an inaccessible species is called a synthetically equivalent group. Often the concept of “umpolung” is involved in devising synthetic equivalent groups. The term *umpolung* refers to the formal reversal of the normal polarity of a functional group.³ Acyl groups are normally *electrophilic*, but a synthetic operation may require the transfer of an acyl group as a *nucleophile*. The *acyl anion* is an umpolung equivalent of the electrophilic acylium cation.

³ For a general discussion and many examples of the use of the umpolung concept, see D. Seebach, *Angew. Chem. Int. Ed. Engl.*, **18**, 239 (1979).

Owing to the great importance of carbonyl groups in synthesis, a substantial effort has been devoted to developing nucleophilic equivalents for introduction of acyl groups.⁴ One successful method involves a three-step sequence in which an aldehyde is converted to an O-protected cyanohydrin. The α -alkoxynitrile is then deprotonated, generating a nucleophilic carbanion **A**.⁵ After carbon-carbon bond formation, the carbonyl group can be regenerated by hydrolysis of the cyanohydrin. This sequence has been used to solve the problem of introducing an acetyl group at the β -position of cyclohexenone.⁶

Ref. 5

α -Lithiovinyl ethers and the corresponding cuprates are other examples of acyl anion equivalents.

Ref. 7

Ref. 8

These reagents are capable of adding the α -alkoxyvinyl group to electrophilic centers. Subsequent hydrolysis can generate the carbonyl group and complete the desired transformation.

Lithiation of vinyl thioethers⁹ and vinyl carbamates¹⁰ also provides acyl anion equivalents.

Sulfur compounds are useful as nucleophilic acyl equivalents. The most common reagents of this type are 1,3-dithianes, which on lithiation provide a nucleophilic acyl equivalent. In dithianes an umpolung is achieved on the basis of the carbanion-stabilizing ability of the sulfur substituents. The lithio derivative is a reactive nucleophile toward alkyl halides and carbonyl compounds.¹¹

1,3-Dithianes have found considerable application in multistep syntheses.¹²

Scheme 13.1 summarizes some examples of synthetic sequences that employ acyl anion equivalents. Another synthetic equivalent that has been extensively developed

corresponds to the propanal “homoenolate,” ${}^{-}\text{CH}_2\text{CH}_2\text{CH}=\text{O}$.¹³ This structure is the umpolung equivalent of an important electrophilic reagent, the, α,β -unsaturated aldehyde acrolein. Scheme 13.2 illustrates some of the propanal homoenolate equivalents that have been developed. In general, the reagents used for these transformations are reactive toward electrophiles such as alkyl halides and carbonyl compounds. Several general points can be made about the reagents in Scheme 13.2. First, it should be noted that they all deliver the aldehyde functionality in a masked form, such as an acetal or enol ether. The aldehyde is liberated in a final step from the protected precursor. Several of the reagents involve delocalized allylic anions, which gives rise to the possibility of electrophilic attack at either the α - or γ -position of the allylic group. In most cases, the γ -attack that is necessary for the anion to function as a propanal homoenolate is dominant. In Entry 1, the 2-methoxycyclopropyllithium is used to form a cyclopropyl carbinol. The methoxy group serves both to promote fragmentation of the cyclopropyl ring and to establish the aldehyde oxidation level. In Entry 2, the lithiation product of allyl methyl ether serves as a nucleophile and the aldehyde group is liberated by hydrolysis. Entry 3 is similar, but uses a trimethylsilyl ether. In Entry 4, allylic lithiation of an *N*-allylamine provides a nucleophile and can subsequently be hydrolyzed to the aldehyde.

In Entry 5, the carbanion-stabilizing ability of the sulfonyl group enables lithiation and is then reductively removed after alkylation. The reagent in Entry 6 is prepared by dilithiation of allyl hydrosulfide using *n*-butyllithium. After nucleophilic addition and S-alkylation, a masked aldehyde is present in the form of a vinyl thioether. Entry 7 uses the epoxidation of a vinyl silane to form a γ -hydroxy aldehyde masked as a cyclic acetal. Entries 8 and 9 use nucleophilic cuprate reagents to introduce alkyl groups containing aldehydes masked as acetals.

The concept of developing reagents that are the synthetic equivalent of inaccessible species can be taken another step by considering dipolar species. For example, structures **B** and **C** incorporate both electrophilic and nucleophilic centers. Such reagents might be incorporated into ring-forming schemes, since they have the ability, at least formally, of undergoing cycloaddition reactions.

Among the real chemical species that have been developed along these lines are the cyclopropyl phosphonium ions **1** and **2**.

The phosphonium salt **1** reacts with β -ketoesters and β -ketoaldehydes to give excellent yields of cyclopentenecarboxylate esters.

Ref. 14

14. W. G. Dauben and D. J. Hart, *J. Am. Chem. Soc.*, **99**, 7307 (1977).

Several steps are involved in these reactions. First, the enolate of the β -ketoester opens the cyclopropane ring. The polarity of this process corresponds to that in the formal synthon **B** because the cyclopropyl carbons are electrophilic. The product of the ring-opening step is a stabilized Wittig ylide, which can react with the ketone carbonyl to form the carbocyclic ring.

The phosphonium ion **2** reacts similarly with enolates to give vinyl sulfides. The vinyl sulfide group can then be hydrolyzed to a ketone. The overall transformation corresponds to the reactivity of the dipolar synthon **C**.

Ref. 16

Many other examples of synthetic equivalent groups have been developed. For example, in Chapter 6 we discussed the use of diene and dienophiles with masked functionality in the Diels-Alder reaction. It should be recognized that there is no absolute difference between what is termed a “reagent” and a “synthetic equivalent group.” For example, we think of potassium cyanide as a reagent, but the cyanide ion is a nucleophilic equivalent of a carboxy group. This reactivity is evident in the classical preparation of carboxylic acids from alkyl halides via nitrile intermediates.

The important point is that synthetic analysis and planning should not be restricted to the specific functionalities that appear in the target molecules. These groups can be incorporated as masked equivalents by methods that would not be possible for the functional group itself.

13.1.3. Control of Stereochemistry

The degree of control of stereochemistry that is necessary during synthesis depends on the nature of the molecule and the objective of the synthesis. The issue

¹⁵. P. L. Fuchs, *J. Am. Chem. Soc.*, **96**, 1607 (1974).

¹⁶. J. P. Marino and R. C. Landick, *Tetrahedron Lett.*, 4531 (1975).

becomes critically important when the target molecule has several stereogenic centers, such as double bonds, ring junctions, and asymmetric carbons. The number of possible stereoisomers is 2^n , where n is the number of stereogenic centers. Failure to control stereochemistry of intermediates in the synthesis of a compound with several centers of stereochemistry leads to a mixture of stereoisomers that will, at best, result in a reduced yield of the desired product and may generate inseparable mixtures. For properties such as biological activity, obtaining the correct stereoisomer is crucial.

We have considered stereoselectivity for many of the reactions that are discussed in the earlier chapters. In ring compounds, for example, stereoselectivity can frequently be predicted on the basis of conformational analysis of the reactant and consideration of the steric and stereoelectronic factors that influence reagent approach. In the *diastereoselective synthesis* of a chiral compound in racemic form, it is necessary to control the *relative configuration* of all stereogenic centers. Thus in planning a synthesis, the stereochemical outcome of all reactions that form new double bonds, ring junctions, or asymmetric carbons must be incorporated into the synthetic plan. In a completely stereoselective synthesis, each successive stereochemical feature is introduced in the proper relationship to existing stereocenters, but this ideal is often difficult to achieve. When a reaction is not completely stereoselective, the product will contain one or more diastereomers of the desired product. This requires either a purification or some manipulation to correct the stereochemistry. Fortunately, diastereomers are usually separable, but the overall efficiency of the synthesis is decreased with each such separation. Thus, high stereoselectivity is an important goal of synthetic planning.

If the compound is to be obtained in enantiomerically pure form, an *enantioselective synthesis* must be developed. As discussed in Section A.2.5, the stereochemical control may be based on chirality in the reactants, auxiliaries, reagents, and/or catalysts. There are several general approaches that are used to obtain enantiomerically pure material by synthesis. One is based on incorporating a *resolution* into the synthetic plan. This approach involves use of racemic or achiral starting materials and resolving some intermediate in the synthesis. In a synthesis based on a resolution, the steps subsequent to the resolution step must meet two criteria: (1) they must not disturb the configuration at existing stereocenters, and (2) new centers of stereochemistry must be introduced with the correct configuration relative to those that already exist. A second general approach is to use an *enantiomerically pure starting material*. Highly enantioselective reactions, such as the Sharpless epoxidation, can be used to prepare enantiomerically pure starting materials. There are a number of naturally occurring materials, or substances derived from them, that are available in enantiomerically pure form.¹⁷

Enantioselective synthesis can also be based on *chiral reagents*. Examples are hydroboration or reduction using one of the commercial available borane reagents. Again, a completely enantioselective synthesis must be capable of controlling the stereochemistry of all newly introduced stereogenic centers so that they have the proper relationship to the chiral centers that exist in the starting material. When this is not achieved, the desired stereoisomer must be separated and purified. A fourth method for enantioselective synthesis involves the use of a stoichiometric amount of a *chiral auxiliary*. This is an enantiomerically pure material that can control the stereochemistry of one or more reaction steps in such a way as to give product having the desired configuration. When the chiral auxiliary has achieved its purpose, it can be

¹⁷. For a discussion of this approach to enantioselective synthesis, see S. Hanessian, *Total Synthesis of Natural Products: The Chiron Approach*, Pergamon Press, New York, 1983.

eliminated from the molecule. As in syntheses involving resolution or enantiomerically pure starting materials, subsequent steps must give the correct configuration of newly created stereocenters. Another approach to enantioselective synthesis is to use a *chiral catalyst* in a reaction that creates one or more stereocenters. If the catalyst operates with complete efficiency, an enantiomerically pure material will be obtained. Subsequent steps must control the configuration of newly introduced stereocenters.

In practice, any of these approaches might be the most effective for a given synthesis. If they are judged on the basis of absolute efficiency in the use of a chiral material, the ranking is resolution < chiral reactant < chiral reagent < chiral auxiliary < enantioselective catalyst. A resolution process inherently employs only half of the original racemic material. A chiral starting material can, in principle, be used with 100% efficiency, but it is consumed and cannot be reused. A chiral reagent is also consumed, but in principle it can be regenerated, as is done for certain organoboranes (see p. 350). A chiral auxiliary must be used in a stoichiometric amount but it can be recovered. A chiral catalyst, in principle, can produce an unlimited amount of an enantiomerically pure material.

The key issue for synthesis of pure stereoisomers, in either racemic or enantiomerically pure form, is that the configuration at newly created stereocenters be controlled in some way. This can be accomplished by several different methods. Existing functional groups may exert a steric or stereoelectronic influence on the reaction center. For instance, an existing functional group may control the approach of a reagent by coordination, which occurs, for example, in hydroxy-directed cyclopropanation (see p. 919). An existing chiral center may control reactant conformation and, thereby, the direction of approach of a reagent.

Generally, the closer the reaction occurs to an existing stereogenic center, the more likely the reaction is to exhibit high stereoselectivity. For example, the creation of adjacent stereogenic centers in aldol and organometallic addition reactions is generally strongly influenced by adjacent substituents leading to a preference for a *syn* or *anti* disposition of the new substituent. We also encountered some examples of *1,3-asymmetric induction*, as, for example, the role of chelates in reduction of β -hydroxy ketones (p. 412), in chelation control of Mukaiyama addition reactions (p. 94), and in hydroboration (Section p. 342). More remote chiral centers are less likely to influence stereoselectivity and examples of, e.g., 1,4- and 1,5-asymmetric induction, are less common. Whatever the detailed mechanism, the synthetic plan must include the means by which the required stereochemical control is to be achieved. If this cannot be done, the price to be paid is a separation of stereoisomers and the resulting reduction in overall yield.

13.2. Illustrative Syntheses

In this section, we consider several syntheses of six illustrative compounds. We examine the retrosynthetic plans and discuss crucial bond-forming steps and the means of stereochemical control. In this discussion, we have the benefit of hindsight in being able to look at successfully completed syntheses. This retrospective analysis can serve to illustrate the issues that arise in planning a synthesis and provide examples of solutions that have been developed. The individual syntheses also provide many examples of the synthetic transformations presented in the previous chapters and of the use of protective groups in the synthesis of complex molecules. The syntheses shown

span a period of several decades and in some cases new reagents and protocols may have been developed since a particular synthesis was completed. Owing to limitations of space, only key steps are discussed although all the steps are shown in the schemes. Usually, only the reagent is shown, although other reaction components such as acids, bases, or solvents may also be of critical importance to the success of the reaction.

13.2.1. Juvabione

Juvabione is a terpene-derived ketoester that has been isolated from various plant sources. There are two stereoisomers, both of which occur naturally with *R*-configuration at C(4) of the cyclohexene ring and are referred to as *erythro*- and *threo*-juvabione. The 7(*S*)-enantiomer is sometimes called epijuvabione. Juvabione exhibits “juvenile hormone” activity in insects; that is, it can modify the process of metamorphosis.¹⁸

In considering the retrosynthetic analysis of juvabione, two factors draw special attention to the bond between C(4) and C(7). First, this bond establishes the stereochemistry of the molecule. The C(4) and C(7) carbons are stereogenic centers and their relative configuration determines the diastereomeric structure. In a stereocontrolled synthesis, it is necessary to establish the desired stereochemistry at C(4) and C(7). The C(4)–C(7) bond also connects the side chain to the cyclohexene ring. As a cyclohexane derivative is a logical candidate for one key intermediate, the C(4)–C(7) bond is a potential bond disconnection.

Other bonds that merit attention are those connecting C(7) through C(11). These could be formed by one of the many methods for the synthesis of ketones. Bond disconnections at carbonyl centers can involve the O=C–C(α) (acylation, organometallic addition), the C(α)–C(β) bond (enolate alkylation, aldol addition), or C(β)–C(γ) bond (conjugate addition to enone).

The only other functional group is the conjugated unsaturated ester. This functionality is remote from the stereocenters and the ketone functionality, and does not play a key role in most of the reported syntheses. Most of the syntheses use cyclic starting materials. Those in Schemes 13.4 and 13.5 lead back to a *para*-substituted aromatic ether. The syntheses in Schemes 13.7 and 13.8 begin with an accessible terpene intermediate. The syntheses in Schemes 13.10 and 13.11 start with cyclohexenone. Scheme 13.3 presents a retrosynthetic analysis leading to the key intermediates used for the syntheses in

¹⁸. For a review, see Z. Wimmer and M. Romanuk, *Coll. Czech. Chem. Commun.*, **54**, 2302 (1989).

Schemes 13.4 and 13.5. These syntheses use achiral reactants and provide mixtures of both stereoisomers. The final products are racemic. The first disconnection is that of the ester functionality, which corresponds to a strategic decision that the ester group can be added late in the synthesis. Disconnection **2** identifies the C(9)–C(10) bond as one that can be formed by addition of some nucleophilic group corresponding to C(10)–C(13) to the carbonyl center at C(9). This corresponds to disconnection α shown above. The third retrosynthetic transform recognizes that the cyclohexanone ring could be obtained by a Birch reduction of an appropriately substituted aromatic ether. The methoxy substituent would provide for correct placement of the cyclic carbonyl group. The final disconnection identifies a simple starting material, 4-methoxyacetophenone.

A synthesis corresponding to this pattern that is shown in Scheme 13.4 relies on well-known reaction types. The C(4)–C(7) bond was formed by a Reformatsky reaction. The adduct was dehydrated during work-up and the product was hydrogenated after purification. The ester group was converted to the corresponding aldehyde by Steps **B-1** through **B-4**. Step **B-5** introduced the C(10)–C(13) isobutyl group by Grignard addition to an aldehyde. In this synthesis, the relative configuration at C(4) and C(7) was established by the hydrogenation in Step **D**. In principle, this reaction could be diastereoselective if the adjacent chiral center at C(7) strongly influenced the direction of addition of hydrogen. In practice, the reduction was not very selective and a mixture of isomers was obtained. Steps **E** and **F** introduced the C(1) ester group.

The synthesis in Scheme 13.5 also makes use of an aromatic starting material and follows a retrosynthetic plan similar to that in Scheme 13.3. The starting material was 4-methoxybenzaldehyde. This synthesis was somewhat more convergent in that the entire side chain except for C(14) was introduced as a single unit by a mixed aldol condensation in step **A**. The C(14) methyl was introduced by a copper-catalyzed conjugate addition in Step **B**.

Scheme 13.6 is a retrosynthetic outline of the syntheses in Schemes 13.7 to 13.9. The common feature of these syntheses is the use of terpene-derived starting materials. The use of such a starting material is suggested by the terpenoid structure of juvabione, which can be divided into “isoprene units.”

isoprene units in juvabione

The synthesis shown in Scheme 13.7 used limonene as the starting material ($R = \text{CH}_3$ in Scheme 13.6), whereas Schemes 13.8 and 13.9 use the corresponding aldehyde ($R = \text{CH=O}$). The use of these starting materials focuses attention on the means of attaching the C(9)–C(13) side chain. Furthermore, since the starting material is an enantiomerically pure terpene, enantioselectivity controlled by the chiral center at C(4) of the starting material might be feasible. In the synthesis in Scheme 13.7, the C(4)–C(7) stereochemistry was established in the hydroboration that is the first step of the synthesis. This reaction showed only very modest stereoselectivity and a 3:2 mixture of diastereomers was obtained and separated. The subsequent steps do not affect these stereogenic centers. The side chain was elaborated by adding *i*-butyllithium to a nitrile. The synthesis in Scheme 13.7 used a three-step oxidation sequence to oxidize the C(15) methyl group to a carboxy group. The first reaction was oxidation

by singlet oxygen to give a mixture of hydroperoxides, with oxygen bound mainly at C(2). The mixture was reduced to the corresponding alcohols, which was then oxidized to the acid via an aldehyde intermediate.

In Scheme 13.8, the side chain was added in one step by a borane carbonylation reaction. This synthesis is very short and the first four steps were used to transform the aldehyde group in the starting material to a methyl ester. The stereochemistry at C(4)–C(7) is established in the hydroboration in Step **B**, in which the C(7)–H bond is formed. A 1:1 mixture of diastereomers resulted, indicating that the configuration at C(4) has little influence on the direction of approach of the borane reagent.

Another synthesis, shown in Scheme 13.9, that starts with the same aldehyde (perillaldehyde) was completed more recently. The C(8)–C(9) bond was established by an allylic chlorination and addition of the corresponding zinc reagent to isobutyraldehyde. In this synthesis, the C(7) stereochemistry was established by a homogeneous hydrogenation of a methylene group, but this reaction also produces both stereoisomers.

The first diastereoselective syntheses of juvabione are described in Schemes 13.11 and 13.12. Scheme 13.10 is a retrosynthetic analysis corresponding to these syntheses, which have certain similarities. Both syntheses started with cyclohexenone, there is a general similarity in the fragments that were utilized, although the order of construction differs, and both led to (±)-juvabione.

A key step in the synthesis in Scheme 13.11 was a cycloaddition between an electron-rich ynamine and the electron-poor enone. The cyclobutane ring was then opened in a process that corresponds to retrosynthetic step **10-IIa** \Rightarrow **10-IIIa** in Scheme 13.10. The crucial step for stereochemical control occurs in Step **B**. The stereoselectivity of this step results from preferential protonation of the enamine from the less hindered side of the bicyclic intermediate.

The cyclobutane ring was then cleaved by hydrolysis of the enamine and ring opening of the resulting β -diketone. The relative configuration of the chiral centers is unaffected by subsequent transformations, so the overall sequence is stereoselective. Another key step in this synthesis is Step **D**, which corresponds to the transformation **10-IIa** \Rightarrow **10-Ia** in the retrosynthesis. A protected cyanohydrin was used as a nucleophilic acyl anion equivalent in this step. The final steps of the synthesis in Scheme 13.11 employed the C(2) carbonyl group to introduce the carboxy group and the C(1)–C(2) double bond.

The stereoselectivity achieved in the synthesis in Scheme 13.12 is the result of a preferred conformation for the base-catalyzed oxy-Cope rearrangement in Step **B**. Although the intermediate used in Step **B** was a mixture of stereoisomers, both gave predominantly the desired relative stereochemistry at C(4) and C(7). The stereoselectivity is based on the preferred chair conformation for the TS of the oxy-Cope rearrangement.

Scheme 13.12. Juvabione Synthesis: D. A. Evans and J. V. Nelson^a

a. D. A. Evans and J. V. Nelson, *J. Am. Chem. Soc.*, **102**, 774 (1980).

The synthesis in Scheme 13.13 leads diastereospecifically to the *erythro* stereoisomer. An intramolecular enolate alkylation in Step **B** gave a bicyclic intermediate. The relative configuration of C(4) and C(7) was established by the hydrogenation in Step **C**. The hydrogen is added from the less hindered *exo* face of the bicyclic enone. This reaction is an example of the use of geometric constraints of a ring system to control relative stereochemistry.

The *threo* stereoisomer was the major product obtained by the synthesis in Scheme 13.14. This stereochemistry was established by the conjugate addition in Step **A**, where a significant (4–6:1) diastereoselectivity was observed. The C(4)–C(7) stereochemical relationship was retained through the remainder of the synthesis. The other special features of this synthesis are in Steps **B** and **C**. The mercuric acetate-mediated cyclopropane ring opening was facilitated by the alkoxy substituent.¹⁹ The reduction by NaBH₄ accomplished both demercuration and reduction of the aldehyde group.

Scheme 13.13. Juvabione Synthesis: A. G. Schultz and J. P. Dittami^a

a. A. G. Schultz and J. P. Dittami, *J. Org. Chem.*, **49**, 2615 (1984).

a. D. J. Morgans, Jr., and G. B. Feigelson, *J. Am. Chem. Soc.*, **105**, 5477 (1983).

In Step **C** a dithiane anion was used as a nucleophilic acyl anion equivalent to introduce the C(10)–C(13) isobutyl group.

In the synthesis shown in Scheme 13.15, racemates of both *erythro*- and *threo*-juvabione were synthesized by parallel routes. The isomeric intermediates were obtained in greater than 10:1 selectivity by choice of the *E*- or *Z*-silanes used for conjugate addition to cyclohexenone (Michael–Mukaiyama reaction). Further optimization of the stereoselectivity was achieved by the choice of the silyl substituents. The observed stereoselectivity is consistent with synclinal TSs for the addition of the crotyl silane reagents.

The purified diastereomeric intermediates were then converted to the juvabione stereoisomers.

Except for the syntheses using terpene-derived starting materials (Schemes 13.7, 13.8, and 13.9), the previous juvabione syntheses all gave racemic products. Some of the more recent juvabione syntheses are *enantiospecific*. The synthesis in Scheme 13.16 relied on a chiral sulfoxide that undergoes stereoselective addition to cyclohexenone to establish the correct relative and absolute configuration at C(4) and C(7). The origin of the stereoselectivity is a chelated TS that leads to the observed product.²⁰

²⁰. M. R. Binns, R. K. Haynes, A. G. Katsifis, P. A. Schober, and S. C. Vonwiller, *J. Am. Chem. Soc.*, **110**, 5411 (1988).

Scheme 13.15. Juvabione Synthesis: T. Tokoroyama and L.-R. Pan^a

a. T. Tokoroyama and L.-R. Pan, *Tetrahedron Lett.*, **30**, 197 (1989).

The sulfoxide substituent was also used to introduce the C(10)–C(13) fragment and was reduced to a vinyl sulfide in Step B-1. In Step C-1, the vinyl sulfide was hydrolyzed to an aldehyde, which was elaborated by addition of isobutylmagnesium bromide.

Scheme 13.17 depicts a synthesis based on enantioselective reduction of bicyclo[2.2.2]octane-2,6-dione by Baker's yeast.²¹ This is an example of desymmetrization (see Part A, Topic 2.2). The unreduced carbonyl group was converted to an alkene by the Shapiro reaction. The alcohol was then reoxidized to a ketone. The enantiomerically pure intermediate was converted to the lactone by Baeyer-Villiger oxidation and an allylic rearrangement. The methyl group was introduced stereoselectively from the *exo* face of the bicyclic lactone by an enolate alkylation in Step C-1.

Scheme 13.16. Juvabione Synthesis: H. Watanabe, H. Shimizu, and K. Mori^a

a. E. Nagano and K. Mori, *Biosci. Biotechnol. Biochem.*, **56**, 1589 (1992).

A final crucial step in this synthesis was an anionic [2,3]-sigmatropic rearrangement of an allylic ether in Step **D**-4 to introduce the C(1) carbon.

Another enantioselective synthesis, shown in Scheme 13.18, involves a early kinetic resolution of the alcohol intermediate in Step **B**-2 by lipase PS. The stereochemistry at the C(7) methyl group is controlled by the *exo* selectivity in the conjugate addition (Step **D**-1).

The bicyclic ring is then cleaved by a Baeyer-Villiger reaction in Step **D**-2. Another interesting feature of this synthesis is the ring expansions used in sequences **A** and **F**. Trimethylsilyl enol ethers were treated with Simmons-Smith reagent to form cyclopropyl silyl ethers. These undergo oxidative cleavage and ring expansion when treated with FeCl_3 and the α -chloro ketones are then dehydrohalogenated by DBU.²²

Scheme 13.18. Juvabione Synthesis: K. Ogasawara and Co-workers^a

a. H. Nagata, T. Taniguchi, M. Kawamura, and K. Ogasawara, *Tetrahedron Lett.*, **40**, 4207 (1999).

The juvabione synthesis in Scheme 13.19 employed both the regiochemical and stereochemical features of the starting material, the $\text{Cr}(\text{CO})_3$ complex of 4-methoxyphenyltrimethylsilane. The lithium enolate of *t*-butyl propanoate was added, resulting in a 96:4 ratio of *meta:ortho* adducts. The addition was also highly stereoselective, giving a greater than 99:1 preference for the *erythro* stereochemistry. This is consistent with reaction through TS **18-A** in preference to TS **18-B** to avoid a *gauche* interaction between the enolate methyl and the trimethylsilyl substituent.

a. N. Soldermann, J. Velker, O. Vallat, H. Stoeckli-Evans, and R. Neier, *Helv. Chim. Acta*, **83**, 2266 (2000).

The reaction product was converted to an intermediate that had previously been converted to *erythro*-juvabione.

The synthesis in Scheme 13.20 features a tandem Diels-Alder reaction and Ireland-Claisen [3,3]-sigmatropic shift as the key steps. Although this strategy was very efficient in constructing the carbon structure, it was not very stereoselective. The major isomer results from an *endo* TS for the Diels-Alder reaction and a [3,3]-sigmatropic rearrangement through a boat TS. Three stereoisomers were obtained in the ratio 47:29:24. These were not separated but were converted to a 4:1 mixture of (\pm) -juvabione and (\pm) -epijuvabione by Arndt-Eistert homologation, DBU-based conjugation, and addition of the isobutyl group by a $\text{Fe}(\text{acac})_3$ -catalyzed Grignard addition.

The synthesis in Scheme 13.21 starts with a lactone that is available in enantiomerically pure form. It was first subjected to an enolate alkylation that was stereocontrolled by the convex shape of the *cis* ring junction (Step A). A stereospecific Pd-mediated allylic substitution followed by LiAlH_4 reduction generated the first key intermediate (Step B). This compound was oxidized with NaIO_4 , converted to the methyl ester, and subjected to a base-catalyzed conjugation. After oxidation of the primary alcohol to an aldehyde, a Wittig-Horner olefination completed the side chain.

The enantioselective synthesis in Scheme 13.22 is based on stereoselective reduction of an α, β -unsaturated aldehyde generated from $(-)$ -(*S*)-limonene (Step A). The reduction was done by Baker's yeast and was completely enantioselective. The diastereoselectivity was not complete, generating an 80:20 mixture, but the diastereomeric alcohols were purified at this stage. After oxidation to the aldehyde, the remainder of the side chain was introduced by a Grignard addition. The ester function

Scheme 13.21. Juvabione Synthesis: E. J Bergner and G. Helmchen^a

a. E. J. Bergner and G. Helmchen, *J. Org. Chem.*, **65**, 5072 (2000).

was introduced by a base-catalyzed opening of the epoxide to an allylic alcohol (Step C-4), which then underwent oxidation with allylic transposition (Step D-1).

Several other syntheses of juvabione have also been completed.²³

13.2.2. Longifolene

Longifolene is a tricyclic sesquiterpene. It is a typical terpene hydrocarbon in terms of the structural complexity. The synthetic challenge lies in construction of the bicyclic ring system. Schemes 13.24 through 13.33 describe nine separate syntheses of longifolene. We wish to particularly emphasize the methods for carbon-carbon bond formation used in these syntheses. There are four stereogenic centers in longifolene,

Scheme 13.22. Juvabione Synthesis. C. Fuganti and S. Serra^a

L. Macdonald, and V. H. Powell, *J. Chem. Soc. C*, 1469 (1970); B. M. Trost and Y. Tamaru, *Tetrahedron Lett.*, 3797 (1975); M. Fujii, T. Aida, M. Yoshihara, and A. Ohno, *Bull. Chem. Soc. Jpn.*, **63**, 1255 (1990).

but they are not independent of one another because the geometry of the ring system requires that they have a specific relative relationship. That does not mean stereochemistry can be ignored, however, since the formation of the various rings will fail if the reactants do not have the proper stereochemistry.

The first successful synthesis of longifolene was described in detail by E. J. Corey and co-workers in 1964. Scheme 13.23 presents a retrosynthetic analysis corresponding to this route. A key disconnection is made on going from **23-I** \Rightarrow **23-II**. This transformation simplifies the tricyclic to a bicyclic skeleton. For this disconnection to correspond to a reasonable synthetic step, the functionality in the intermediate to be cyclized must engender mutual reactivity between C(7) and C(10). This is achieved in diketone **23-II**, because an enolate generated by deprotonation at C(10) can undergo an intramolecular Michael addition to C(7). The stereochemistry requires that the ring junction be *cis*. Retrosynthetic Step **23-II** \Rightarrow **23-III** is attractive because it suggests a decalin derivative as a key intermediate. Methods for preparing this type of structure are well developed, since they are useful intermediates in the synthesis of other terpenes as well as steroids. Can a chemical reaction be recognized that would permit **23-III** \Rightarrow **23-II** to proceed in the synthetic sense? The hydroxy to carbonyl transformation with migration corresponds to the pinacol rearrangement (Section 10.1.2.1). The retrosynthetic transformation **23-II** \Rightarrow **23-III** corresponds to a workable synthetic step if the group X in **23-III** is a leaving group that could promote the rearrangement. The other transformations in the retrosynthetic plan, **23-III** \Rightarrow **23-IV** \Rightarrow **23-V**, are straightforward in concept and lead to identification of **23-V** as a potential starting material.

Scheme 13.23. Retrosynthesis of Longifolene Corresponding to the Synthesis in Scheme 13.24

a. E. J. Corey, M. Ohno, R. B. Mitra, and P. A. Vatakencherry, *J. Am. Chem. Soc.*, **86**, 478 (1964).

Compound **23-V** is known as the Wieland-Miescher ketone and can be obtained by Robinson annulation of 2-methylcyclohexane-1,3-dione.

The synthesis was carried out as shown in Scheme 13.24. A diol was formed and selectively tosylated at the secondary hydroxy group (Step A-4). Base then promoted the skeletal rearrangement in Step B-1 by a pinacol rearrangement corresponding to **23-II** \Rightarrow **23-III** in the retrosynthesis. The key intramolecular Michael addition was accomplished using triethylamine under high-temperature conditions.

The cyclization requires that the intermediate have a *cis* ring fusion. The stereochemistry of the ring junction was established when the double bond was moved into conjugation in Step B-2. The product was not stereochemically characterized, and need not be, because the stereochemically important site at C(1) can be epimerized under the basic cyclization conditions. Thus, the equilibration of the ring junction through a dienol allows the cyclization to proceed to completion from either stereoisomer.

After the crucial cyclization in Step C, the subsequent transformations effect the addition of the remaining methyl and methylene groups by well-known methods. Step E accomplishes a selective reduction of one of the two carbonyl groups to a methylene by taking advantage of the difference in the steric environment of the two carbonyls. Selective protection of the less hindered C(5) carbonyl was done using a thioketal. The C(11) carbonyl was then reduced to give the alcohol, after which C(5) was reduced to a methylene group under Wolff-Kishner conditions. The hydroxy group at C(11) provided the reactive center necessary to introduce the C(15) methylene group via methyllithium addition and dehydration in Step F.

The Wieland-Miescher ketone was also the starting material for the synthesis in Scheme 13.25. The key bond closure was performed on a bicyclo[4.4.0]decane ring system. An enolate was used to open an epoxide ring in Step B-2. The ring juncture must be *cis* to permit the intramolecular epoxide ring opening. The required *cis* ring fusion was established during the catalytic hydrogenation in Step A.

a. J. E. McMurry and S. J. Isser, *J. Am. Chem. Soc.*, **94**, 7132 (1972).

The key cyclization in Step **B-2** was followed by a sequence of steps that effected a ring expansion via a carbene addition and cyclopropyl halide solvolysis. The products of Steps **E** and **F** are interesting in that the tricyclic structures are largely converted to tetracyclic derivatives by intramolecular aldol reactions. The extraneous bond was broken in Step **G**. First a diol was formed by NaBH_4 reduction and this was converted via the lithium alkoxide to a monomesylate. The resulting β -hydroxy mesylate is capable of a concerted fragmentation, which occurred on treatment with potassium *t*-butoxide.

Longifolene has also been synthesized from (\pm) Wieland-Miescher ketone by a series of reactions that feature an intramolecular enolate alkylation and ring expansion, as shown in Scheme 13.26. The starting material was converted to a dibromo ketone via the *bis*-silyl enol ether in the first sequence of reactions. This intermediate underwent an intramolecular enolate alkylation to form the C(7)–C(10) bond. The ring expansion was then done by conversion of the ketone to a silyl enol ether, cyclopropanation, and treatment of the siloxycyclopropane with FeCl_3 .

The final stages of the synthesis involved introduction of the final methyl group by Simmons-Smith cyclopropanation and reductive opening of the cyclopropane ring.

A retrosynthetic analysis corresponding to the synthesis in Scheme 13.28 is given in Scheme 13.27. The striking feature of this synthesis is the structural simplicity of the key intermediate **27-IV**. A synthesis according to this scheme generates the tricyclic skeleton in a single step from a monocyclic intermediate. The disconnection **27-III**–**27-IV** corresponds to a cationic cyclization of the highly symmetric allylic cation **27-IVa**.

No issues of stereochemistry arise until the carbon skeleton is formed, at which point all of the stereocenters are in the proper relative relationship. The structures of the successive intermediates, assuming a stepwise mechanism for the cationic cyclization, are shown below.

Scheme 13.26. Longifolene Synthesis: S. Karimi and P. Tavares^a

a. S. Karimi, *J. Nat. Prod.*, **64**, 406 (2001); S. Karimi and P. Tavares, *J. Nat. Prod.*, **66**, 520 (2003).

Evidently, these or closely related intermediates are accessible and reactive, since the synthesis was successfully achieved as outlined in Scheme 13.28. In addition to the key cationic cyclization in Step **D**, interesting transformations were carried out in Step **E**, where a bridgehead tertiary alcohol was reductively removed, and in Step **F**, where a methylene group, which was eventually reintroduced, had to be removed. The endocyclic double bond, which is strained because of its bridgehead location, was isomerized to the exocyclic position and then cleaved with $\text{RuO}_4/\text{IO}_4^-$. The enolate of the ketone was then used to introduce the C(12) methyl group in Steps **F**-3 and **F**-4.

The synthesis in Scheme 13.29 also uses a remarkably simple starting material to achieve the construction of the tricyclic skeleton. A partial retrosynthesis is outlined below.

Scheme 13.28. Longifolene Synthesis: W. S. Johnson and Co-Workers^a

Scheme 13.29. Longifolene Synthesis: W. Oppolzer and T. Godel^a

a. W. Oppolzer and T. Godel, *J. Am. Chem. Soc.*, **100**, 2583 (1978); W. Oppolzer and T. Godel, *Helv. Chim. Acta*, **67**, 1154 (1984).

Intermediate **29-I** contains the tricyclic skeleton of longifolene, shorn of its substituents, but containing carbonyl groups suitably placed so that the methyl groups at C(2) and C(6) and the C(11) methylene can be introduced. The retrosynthetic Step **29-I** \Rightarrow **29-II** corresponds to an intramolecular aldol addition. However, **29-II** is clearly strained relative to **29-I**, and so (with OR = OH) should open to **29-I**.

How might **29-II** be obtained? The four-membered ring suggests that a photochemical [2+2] cycloaddition might be useful, and this, in fact, was successful (Scheme 13.29, Step B). The cyclopentanone intermediate was converted to an enol carbonate. After photolysis, the carbobenzyloxy group was removed by hydrogenolysis, which led to opening of the strained aldol to the diketone intermediate. After liberation of the hydroxy group, the extra carbon-carbon bond between C(2) and C(6) was broken by a spontaneous retro-aldol reaction. Step D in this synthesis is an interesting way of introducing the geminal dimethyl groups. It proceeds through a cyclopropane intermediate that is cleaved by hydrogenolysis. In Step E, the C(12) methyl group was introduced by enolate alkylation and the C(15) methylene group was installed by a Wittig reaction.

The synthesis of longifolene in Scheme 13.30 commenced with a Birch reduction and tandem alkylation of methyl 2-methoxybenzoate (see Section 5.6.1.2). Step C is an intramolecular cycloaddition of a diazoalkane that is generated from an aziridinoimine intermediate.

The thermolysis of the adduct in Step D generates a diradical (or the corresponding dipolar intermediate), which then closes to the desired carbon skeleton.

The cyclization product was converted to an intermediate that was used in the longifolene synthesis described in Scheme 12.24.

The synthesis in Scheme 13.30 was also done in such a way as to give enantiomerically pure longifolene. A starting material, whose chirality is derived from the amino acid L-proline, was enantioselectively converted to the product of Step A in Scheme 13.30.

This chiral intermediate, when carried through the reaction sequence in Scheme 13.30, generated the enantiomer of natural longifolene. Thus D-proline would have to be used to generate the natural enantiomer.

Scheme 13.30. Longifolene Synthesis: A. G. Schultz and S. Puig^a

a. A. G. Schultz and S. Puig, *J. Org. Chem.*, **50**, 915 (1985).

An enantiospecific synthesis of longifolene was done starting with camphor, a natural product available in enantiomerically pure form (Scheme 13.31). The tricyclic ring was formed in Step C by an intramolecular Mukaiyama reaction. The dimethyl substituents were formed in Step E-1 by hydrogenolysis of the cyclopropane ring. The final step of the synthesis involved a rearrangement of the tricyclic ring that was induced by solvolysis of the mesylate intermediate.

Another enantiospecific synthesis of longifolene shown in Scheme 13.32 used an intramolecular Diels-Alder reaction as a key step. An alcohol intermediate was resolved in sequence B by formation and separation of a menthyl carbonate. After oxidation, the dihydropyrone ring was introduced by γ -addition of the ester enolate of methyl 3-methylbutenoate, followed by cyclization.

The dihydropyrone ring then served as the dienophile in the intramolecular Diels-Alder (IMDA) cycloaddition that was conducted in a microwave oven. The cyclopentadiene

Scheme 13.31. Longifolene Synthesis: D. L. Kuo and T. Money^a

a. B. Lei and A. G. Fallis, *J. Am. Chem. Soc.*, **112**, 4609 (1990); B. Lei and A. G. Fallis, *J. Org. Chem.*, **58**, 2186 (1993).

ring permits rapid equilibration of the diene isomers by 1,5-hydrogen shifts and the most stable IMDA TS leads to the desired product.

The final step of this synthesis used a high-temperature acetate pyrolysis to introduce the exocyclic double bond of longifolene.

Scheme 13.33 shows broad retrosynthetic formulations of the longifolene syntheses that are discussed in this subsection. Four different patterns of bond formation are represented. In **A**, the C(7)–C(10) bond is formed from a bicyclic intermediate. This pattern corresponds to the syntheses in Schemes 13.24, 13.25, 12.26, and 13.29. In retrosynthesis **B**, there is concurrent formation of the C(1)–C(2) and C(10)–C(11) bonds, as in the synthesis in scheme 13.28. This is also the pattern found in the synthesis in Scheme 13.32. The synthesis in Scheme 13.29 corresponds to retrosynthesis **C**, in which the C(1)–C(2) and C(6)–C(7) bonds are formed and an extraneous bond between C(2) and C(5) is broken. Finally, retrosynthesis **D**, corresponding to formation of the C(2)–C(3) bond, is represented by the synthesis in Scheme 13.31.

These syntheses of longifolene provide good examples of the approaches that are available for construction of polycyclic ring compounds. In each case, a set of

Scheme 13.33. Summary of Some Retrosynthetic Patterns in Longifolene Syntheses

functionalities that have the potential for *intramolecular* reaction was assembled. After assembly of the carbon framework, the final functionality changes were effected. It is the necessity for the formation of the carbon skeleton that determines the functionalities that are present at the ring-closure stage. After the ring structure is established, necessary adjustments of the functionalities are made.

13.2.3. Prelog-Djerassi Lactone

The Prelog-Djerassi lactone (abbreviated here as P-D lactone) was originally isolated as a degradation product during structural investigations of antibiotics. Its open-chain equivalent **3** is typical of the methyl-branched carbon chains that occur frequently in macrolide and polyether antibiotics. The compound serves as a test case for the development of methods of control of stereochemistry in such polymethylated structures. There have been more than 20 different syntheses of P-D lactone.²⁴ We focus here on some of those that provide enantiomerically pure product, as they illustrate several of the methods for enantioselective synthesis.²⁵

²⁴. For references to many of these syntheses, see S. F. Martin and D. G. Guinn, *J. Org. Chem.*, **52**, 5588 (1987); H. F. Chow and I. Fleming, *Tetrahedron Lett.*, **26**, 397 (1985); S. F. Martin and D. E. Guinn, *Synthesis*, 245 (1991).

²⁵. For other syntheses of enantiomerically pure Prelog-Djerassi lactone, see F. E. Ziegler, A. Kneisley, J. K. Thottathil, and R. T. Wester, *J. Am. Chem. Soc.*, **110**, 5434 (1988); A. Nakano, S. Takimoto, J. Inanaga, T. Katsuki, S. Ouchida, K. Inoue, M. Aiga, N. Okukado, and M. Yamaguchi, *Chem. Lett.*, 1019 (1979); K. Suzuki, K. Tomooko, T. Matsumoto, E. Katayama, and G. Tsuchihashi, *Tetrahedron*

The synthesis in Scheme 13.34 is based on a bicyclic starting material that can be prepared in enantiomerically pure form. In the synthesis, C(7) of the norbornenone starting material becomes C(4) of P-D lactone and the methyl group in the starting material becomes the C(4) methyl substituent. The sequence uses the cyclic starting material to control facial selectivity. The configuration of the C(3) hydroxy and C(2) and C(6) methyl groups must be established relative to the C(4) stereocenter. The *exo*-selective alkylation in Step A established the configuration at C(2). The Baeyer-Villiger oxidation in Step B was followed by a Lewis acid-mediated allylic rearrangement, which is suprafacial. This stereoselectivity is dictated by the preference for maintaining a *cis* ring juncture at the five-membered rings.

The stereochemistry of the C(3) hydroxy was established in Step D. The Baeyer-Villiger oxidation proceeds with retention of configuration of the migrating group (see Section 12.5.2), so the correct stereochemistry is established for the C–O bond. The final stereocenter for which configuration must be established is the methyl group at C(6) that was introduced by an enolate alkylation in Step E, but this reaction was not very stereoselective. However, since this center is adjacent to the lactone carbonyl, it can be epimerized through the enolate. The enolate was formed and quenched with acid. The kinetically preferred protonation from the axial direction provides the correct stereochemistry at C(6).

Scheme 13.34. Prelog-Djerassi Lactone Synthesis: P. A. Grieco and Co-Workers^a

a. P. A. Grieco, Y. Ohfuné, Y. Yokoyama, and W. Owens, *J. Am. Chem. Soc.*, **101**, 4749 (1979).

Lett., **26**, 3711 (1985); M. Isobo, Y. Ichikawa, and T. Goto, *Tetrahedron Lett.*, **22**, 4287 (1981); M. Mori, T. Chuman, and K. Kato, *Carbohydrate Res.*, **129**, 73 (1984).

Another synthesis of P-D lactone that is based on an enantiomerically pure starting material is shown in Scheme 13.35. The stereocenter in the starting material is destined to become C(4) in the final product. Steps **A** and **B** served to extend the chain to provide a seven-carbon 1,5-diene. The configuration of two of the three remaining stereocenters is controlled by the hydroboration step, which is a stereospecific *syn* addition (Section 4.5.1). In 1,5-dienes of this type, an intramolecular hydroboration occurs and establishes the configuration of the two newly formed C—B and C—H bonds.

There was, however, no significant selectivity in the initial hydroboration of the terminal double bond. As a result, both configurations are formed at C(6). This problem was overcome using the epimerization process from Scheme 13.34.

The syntheses in Schemes 13.36 to 13.40 are conceptually related. They begin with symmetric achiral derivatives of *meso*-2,4-dimethylglutaric acid and utilize various approaches to the *desymmetrization* of the *meso* starting material. In Scheme 13.36

Scheme 13.35. Prelog-Djerassi Lactone Synthesis: W. C. Still and K. R. Shaw^a

a. W. C. Still and K. R. Shaw, *Tetrahedron Lett.*, **22**, 3725 (1981).

b. Epimerization as in Scheme 13.34.

the starting material was prepared by reduction of the half-ester of *meso*-2,4-dimethylglutaric acid. The use of the *meso*-diacid ensures the correct *relative configuration* of the C(4) and C(6) methyl substituents. The half-acid was resolved and the correct enantiomer was reduced to the aldehyde. The stereochemistry at C(2) and C(3) was established by stereoselective aldol condensation methodology. Both the lithium enolate and the boron enolate methods were employed. The use of bulky enolates enhances the stereoselectivity. The enol derivatives were used in enantiomerically pure form so the condensations are examples of *double stereodifferentiation* (Section 2.1.5.3). The stereoselectivity observed in the reactions is that predicted by a cyclic TS for the aldol condensations.

The synthesis in Scheme 13.37 also used a *meso*-3,4-dimethylglutaric acid as the starting material. Both the resolved aldehyde employed in Scheme 13.36 and a resolved half-amide were successfully used as intermediates. The configuration at C(2) and C(3) was controlled by addition of a butenylborane to an aldehyde (see Section 9.1.5). The boronate was used in enantiomerically pure form so that stereoselectivity was enhanced by *double stereodifferentiation*. The allylic additions carried out by the butenylboronates do not appear to have been quite as highly stereoselective as the aldol condensations used in Scheme 13.37, since a minor diastereoisomer was formed in the boronate addition reactions.

The synthesis in Scheme 13.38 is based on an interesting kinetic differentiation in the reactivity of two centers that are structurally identical, but diastereomeric. A *bis*-amide of *meso*-2,4-dimethylglutaric acid and a chiral thiazoline was formed in Step A. The thiazoline is derived from the amino acid cysteine. The two amide carbonyls in this *bis*-amide are nonequivalent by virtue of the diastereomeric relationship established

b. Resolved via α -phenylethylamine salt; S. Masamune, S. A. Ali, D. L. Snitman, and D. S. Garvey, *Angew. Chem. Int. Ed. Engl.*, **19**, 557 (1980).

by the stereogenic centers at C(2) and C(4) in the glutaric acid portion of the structure. One of the centers reacted with a 97:3 preference with the achiral amine piperidine.

In Step **D** another thiazoline chiral auxiliary, also derived from cysteine, was used to achieve double stereodifferentiation in an aldol addition. A tin enolate was used. The stereoselectivity of this reaction parallels that of aldol reactions carried out with lithium or boron enolates. After the configuration of all the centers was established, the synthesis proceeded to P-D lactone by functional group modifications.

A very short and efficient synthesis based on the desymmetrization principle is shown in Scheme 13.39. *meso*-2,4-Dimethylglutaraldehyde reacted selectively with the diethylboron enolate derived from a bornanesultam chiral auxiliary. This reaction established the stereochemistry at the C(2) and C(3) centers. The dominant aldol product results from an anti-Felkin stereoselectivity with respect to the C(4) center.

a. Y. Nagao, T. Inoue, K. Hashimoto, Y. Hagiwara, M. Ochai, and E. Fujita, *J. Chem. Soc., Chem. Commun.*, 1419 (1985).

The adduct cyclized to a lactol mixture that was oxidized by TPAP-NMMO to give the corresponding lactones in an 8:1 ratio (86% yield). Hydrolysis in the presence of H_2O_2 gave the P-D lactone and recovered chiral auxiliary.

The synthesis in Scheme 13.40 features a catalytic asymmetric epoxidation (see Section 12.2.1.2). By use of *meso*-2,4-dimethylglutaric anhydride as the starting material, the proper relative configuration at C(4) and C(6) is ensured. The epoxidation directed by the (+)-tartrate catalyst controls the configuration established at C(2) and C(3) by the epoxidation. Although the epoxidation is highly selective in

establishing the configuration at C(2) and C(3), the configuration at C(4) and C(6) does not strongly influence the reaction; a mixture of diastereomeric products was formed and then separated at a later stage in the synthesis. The reductive ring opening in Step **D** occurs with dominant inversion to establish the necessary (*R*)-configuration at C(2). The preference for 1,3-diol formation is characteristic of reductive ring opening by Red-Al of epoxides derived from allylic alcohols.²⁶ Presumably, initial coordination at the hydroxy group and intramolecular delivery of hydride is responsible for this stereoselectivity.

The synthesis in Scheme 13.41 is also built on the desymmetrization concept but uses a very different intermediate. *cis*-5,7-Dimethylcycloheptadiene was acetoxyated with $\text{Pd}(\text{OAc})_2$ and the resulting all-*cis*-diacetate intermediate was enantioselectively hydrolyzed with a lipase to give a monoacetate that was protected as the TBDMS ether. An *anti* $\text{S}_{\text{N}}2'$ displacement by dimethyl cuprate established the correct configuration of the C(2) methyl substituent. Oxidative ring cleavage and lactonization gave the final product.

There have been several syntheses of P-D lactone that were based on carbohydrate-derived starting materials. The starting material used in Scheme 13.42 was prepared from a carbohydrate produced in earlier work.²⁷ The relative stereochemistry at C(4)

²⁶ P. Ma, V. S. Martin, S. Masamune, K. B. Sharpless, and S. M. Viti, *J. Org. Chem.*, **47**, 1378 (1982); S. M. Viti, *Tetrahedron Lett.*, **23**, 4541 (1982); J. M. Finan and Y. Kishi, *Tetrahedron Lett.*, **23**, 2719 (1982).

and C(6) was established by the hydrogenation in Step A-2. This *syn* hydrogenation is not completely stereoselective, but provided a 4:1 mixture favoring the desired stereoisomer. The stereoselectivity is presumably the result of preferential absorption from the less hindered β -face of the molecule. The configuration of C(2) was established by protonation during the hydrolysis of the enol ether in Step C-2. This step was not stereoselective, so a separation of diastereomers after the oxidation in Step C-3 was required.

The synthesis in Scheme 13.43 also began with carbohydrate-derived starting material and uses catalytic hydrogenation in Step C-1 to establish the stereochemical relationship between the C(4) and C(6) methyl groups. As was the case in Scheme 13.42, the configuration at C(2) was not controlled in this synthesis and separation of the diastereomeric products was necessary. This synthesis used an organocopper reagent to introduce both the C(4) and C(2) methyl groups. The former was introduced by S_N2' allylic substitution in Step B and the latter by conjugate addition to a nitroalkene in Step D.

The synthesis in Scheme 13.44 is also based on a carbohydrate-derived starting material. It controlled the stereochemistry at C(2) by means of the stereoselectivity of the Ireland-Claisen rearrangement in Step A (see Section 6.4.2.3). The ester enolate was formed under conditions in which the *E*-enolate is expected to predominate. Heating the resulting silyl enol ether gave a 9:1 preference for the expected stereoisomer. The

preferred TS, which is boatlike, minimizes the steric interaction between the bulky silyl substituent and the ring structure.

The stereochemistry at C(4) and C(6) was then established. The cuprate addition in Step C occurred *anti* to the substituent at C(2) of the pyran ring. After a Wittig

methylenation, the catalytic hydrogenation in Step **D** established the stereochemistry at C(6). The lactone carbonyl was introduced by β -elimination and ozonolysis.

The syntheses in Schemes 13.45 and 13.46 illustrate the use of oxazolidinone chiral auxiliaries in enantioselective synthesis. Step **A** in Scheme 13.45 established the configuration at the carbon that becomes C(4) in the product. This is an enolate alkylation in which the steric effect of the oxazolidinone chiral auxiliary directs the approach of the alkylating group. Step **C** also used the oxazolidinone structure. In this case, the enol borinate is formed and condensed with an aldehyde intermediate. This stereoselective aldol addition established the configuration at C(2) and C(3). The configuration at the final stereocenter at C(6) was established by the hydroboration in Step **D**. The selectivity for the desired stereoisomer was 85:15. Stereoselectivity in the same sense has been observed for a number of other 2-methylalkenes in which the remainder of the alkene constitutes a relatively bulky group.²⁸ A TS such as **45-A** can rationalize this result.

In the synthesis in Scheme 13.46, a stereoselective aldol addition was used to establish the configuration at C(2) and C(3) in Step **A**. The furan ring was then subjected to an electrophilic addition and solvolytic rearrangement in Step **B**.

The protection of the hemiacetal hydroxyl in Step B-2 was followed by a purification of the dominant stereoisomer. In Step C-1, the addition of the C(6) methyl group gave predominantly the undesired α -stereoisomer. The enolate was trapped as the trimethylsilyl ether and oxidized to the enone by $\text{Pd}(\text{OAc})_2$. The enone from sequence C was then subjected to a Wittig reaction. As in several of the other syntheses, the hydrogenation in Step D-2 was used to establish the configuration at C(4) and C(6).

The synthesis in Scheme 13.47 was also based on use of a chiral auxiliary and provided the TBDMS-protected derivative of P-D lactone in the course of synthesis of the macrolide portion of the antibiotic 10-deoxymethymycin. The relative stereochemistry at C(2)–C(3) was obtained by addition of the dibutylboron enolate of an *N*-propanoyl oxazolidinone. The addition occurs with *syn* anti-Felkin stereochemistry.

Removal of the chiral auxiliary and reduction gave an intermediate that had differentiated terminal hydroxy groups. Although the sequence was initially carried out on the benzyl or TBDMS-protected aldehyde, with subsequent removal of the protecting group, it was found that the aldol addition could be carried out directly on the tosylate, providing a shorter route. A propanoyl group was added at Step C-1 and provided the remainder of the carbon chain. The lactone ring was closed by an intramolecular enolate alkylation. This step is not highly stereoselective, but equilibration (see Scheme 13.34) gave the desired stereoisomer in a 10:1 ratio.

The synthesis in Scheme 13.48 used stereospecific ring opening of an epoxide by trimethylaluminum to establish the stereochemistry of the C(4) methyl group. The starting material was made by enantiospecific epoxidation of the corresponding allylic alcohol.²⁹ The hydrogenation in Step B-1 achieved about 3:1 stereoselectivity at C(2). Removal of the benzyl protecting group by hydrogenolysis then gave the lactone.

The synthesis in Scheme 13.49 features use of an enantioselective allylic boronate reagent derived from diisopropyl tartrate to establish the C(4) and C(5) stereochemistry. The ring is closed by an olefin metathesis reaction. The C(2) methyl group was introduced by alkylation of the lactone enolate. The alkylation is not stereoselective, but base-catalyzed epimerization favors the desired stereoisomer by 4:1.

Scheme 13.50. Prelog-Djerassi Lactone Synthesis: D. J.-S. Tsai and M. M. Midland^a

a. D. J.-S. Tsai and M. M. Midland, *J. Am. Chem. Soc.*, **107**, 3915 (1985).

The synthesis in Scheme 13.50 used the stereoselectivity of a [2,3]-sigmatropic rearrangement as the basis of stereochemical control. The starting material was prepared by enantioselective reduction of the corresponding ketone using *S*-Alpine-Borane. The sigmatropic rearrangement of the lithium anion in Step **B** gave 97:3 stereoselectivity for the *syn* isomer (see p. 588). After protection, this intermediate was selectively hydroborated with $(\text{C}_6\text{H}_{11})_2\text{BH}$ and converted to the iodide. The hydroboration in Step **C**-2 establishes the stereochemistry at C(4) with 15:1 stereoselectivity. The iodide was then used in conjunction with a chiral auxiliary to create the C(2)–C(3) bond by alkylation of the amide enolate.

A recent synthesis of P-D lactone (Scheme 13.51) used an enantioselective catalytic approach. A conjugate addition of a silyl ketene acetal derived from an unsaturated lactone gave an unsaturated lactone intermediate. The catalyst is $\text{CuF}(\text{S})$ -tol-BINAP.³⁰ The catalytic cycle for the reaction is shown below.

Scheme 13.51. Prelog-Djerassi Lactone Synthesis: J.-M. Campagne and Co-Workers^a

a. G. Bluet, B. Bazan-Tejeda, and J.-M. Campagne, *Org. Lett.*, **3**, 3807 (2001).

³⁰. J. Krueger and E. M. Carreira, *J. Am. Chem. Soc.*, **120**, 837 (1998).

The reaction was very stereoselective for the correct P-D lactone configuration. The synthesis, which is outlined in Scheme 13.51, was completed by the sequence shown in Scheme 13.49.

The synthesis shown in Scheme 13.52 started with an enantiomerically pure protected aldehyde. Reaction with a Grignard reagent installed an allylic silane. This reaction gave a mixture of alcohols, but both were converted to the same intermediate by taking advantage of selective formation of *E*- or *Z*-silyl ketene acetal prior to an Ireland-Claisen rearrangement. These stereoconvergent transformations are described on p. 568). Two subsequent steps are noteworthy. In Step C-3, a BF_3 -mediated opening of the dioxolane ring triggers a desilylation. In Step E-1, the diimide reduction occurs with excellent stereoselectivity. This is attributed to a π -stacking interaction with the TBDPS protecting group, since no similar effect was noted with the TBDMS group.

The final lactonization and oxidation were done as in Scheme 13.40.

The next phase of the synthesis was construction of the C-ring. An aldol addition was used to introduce a 3-butenyl group at C(8) and the product was trapped as a carbonate ester. The Davis oxaziridine was then used to introduce an oxygen at C(2). After reduction of the C(3) oxygen, a cyclic carbonate was formed, and C(2) was converted

to a carbonyl group by Swern oxidation. In Step **D** this carbonate was rearranged to a lactone.

Reaction sequence **E** removed an extraneous oxygen by SmI_2 reduction and installed an oxygen at C(15) by enolate oxidation. The C(1) and C(15) hydroxy groups were protected as a carbonate in Step **E**-5. After oxidation of the terminal vinyl group, the C-ring was constructed by a Dieckmann cyclization in Step **F**-4. After temporary protection of the C(7) hydroxy as the MOP derivative, the β -ketoester was subjected to nucleophilic decarboxylation by phenylthiolate and reprotected as the BOM ether (Steps **F**-5, **F**-6, and **F**-7).

An oxygen substituent was introduced at C(5) by MCPBA oxidation of a silyl enol ether (Steps **G**-1 and **G**-2). An exocyclic methylene group was introduced at C(4) by a methyl Grignard addition followed by dehydration with Burgess reagent (**G**-3). The oxetane ring was constructed in Steps **H**-1 to **H**-4. The double bond was hydroxylated with OsO_4 and a sequence of selective transformations of the triol provided the hydroxy tosylate, which undergoes intramolecular nucleophilic substitution to form the oxetane ring.

In Step **H**-7 the addition of phenyllithium to the cyclic carbonate group neatly generates the C(2) benzoate group. A similar reaction was used in several other Taxol syntheses.

The final phase of the synthesis is introduction of the C(9) oxygen by phenylselenenic anhydride (Step **H**-9) and acetylation.

The Baccatin III synthesis by K. C. Nicolaou and co-workers is summarized in Scheme 13.54. Diels-Alder reactions are prominent in forming the early intermediates. In Step **A** the pyrone ring served as the diene. This reaction was facilitated by phenylboronic acid, which brings the diene and dienophile together as a boronate, permitting an intramolecular reaction.

The formation of the A-ring in Step D used α -chloroacrylonitrile as a ketene synthon. The A-ring and C-ring were brought together in Step G by an organolithium addition to the aldehyde. The lithium reagent was generated by a Shapiro reaction. An oxygen was introduced at C(1) by hydroxy-directed epoxidation in Step H-1 and reductive ring opening of the epoxide in Step H-2. The eight-membered B-ring was then closed by a titanium-mediated reductive coupling of a dialdehyde in Step I-1. The oxetane

a. S. J. Danishefsky, J. J. Masters, W. B. Young, J. T. Link, L. B. Snyder, T. V. Magee, D. K. Jung, R. C. A. Isaacs, W. G. Bornmann, C. A. Alaimo, C. A. Coburn, and M. J. Di Grandi, *J. Am. Chem. Soc.*, **118**, 2843 (1996).

ring was closed in sequence **K** by an intramolecular O-alkylation with inversion at C(5). The C(13) oxygen was introduced late in the synthesis by an allylic oxidation using PCC (Step **L**-3).

The synthesis of S. J. Danishefsky's group is outlined in Scheme 13.55. The starting material is a protected derivative of the Wieland-Miescher ketone. The oxetane ring is formed early in this synthesis. An epoxide is formed using dimethylsulfonium methylide (Step **A**-3) and opened to an allylic alcohol in Step **A**-4. The double bond

was dihydroxylated using OsO_4 . The cyclization occurs via the C(5) triflate and was done in ethylene glycol. After cyclization, the tertiary hydroxy at C(4) was protected by benzylation and the ketal protecting group was removed. The cyclohexanone ring was then cleaved by oxidation of the silyl enol ether. The A-ring was introduced in Step **E** by use of a functionalized lithium reagent. The closure of the B-ring was done by an intramolecular Heck reaction involving a vinyl triflate at Step **G-4**.

The late functionalization included the introduction of the C(10) and C(13) oxygens, which was done by phenylselenenic anhydride oxidation of the enolate in Step **I-5** and by allylic oxidation at C(13) in Step **J-1**. These oxidative steps are similar to transformations in the Holton and Nicolaou syntheses.

The synthesis of the Taxol in Scheme 13.56 by P. A. Wender and co-workers at Stanford University began with an oxidation product of the readily available terpene pinene. One of the key early steps was the photochemical rearrangement in Step **B**.

A six-membered ring was then constructed in reaction sequence **C** by addition of lithiated ethyl propynoate and a tandem conjugate addition-cyclization. The C(10) oxygen was introduced by enolate oxidation in Step **D-2**. Another key step is the fragmentation induced by treatment first with MCPBA and then with DABCO (Steps **E-1** and **E-2**). The four-membered ring is fragmented in the process, forming the eight-membered ring with its bridgehead double bond and providing the C(13) oxygen substituent.

The C(1) oxygen was introduced at Step **F-1** by enolate oxidation. The C-ring was constructed by building up a substituent at C(16) (Steps **G** and **H**). After forming the benzoate at C(2) in Step **H-4**, the C(9) acetoxy ketone undergoes transposition. This is an equilibrium process that goes to about 55% completion. An aldehyde was generated by ozonolysis of the terminal allylic double bond. This group was used to close the C-ring by an aldol cyclization in Step **I-1**. This step completed the construction of the

E. Floreancig, T. E. Glass, J. B. Houze, N. E. Krauss, D. Lee, D. G. Marquess, P. L. McGrane, W. Meng, M. G. Natchus, A. J. Shuker, J. C. Sutton, and R. E. Taylor, *J. Am. Chem. Soc.*, **119**, 2757 (1997).

carbon framework. The synthesis was completed by formation of the oxetane ring by the sequence **I-3** to **I-8**, followed by the cyclization in Step **J-1**.

The synthesis of Baccatin III shown in Scheme 13.57, which was completed by a group led by the Japanese chemist Teruaki Mukaiyama, takes a different approach for the previous syntheses. Much of the stereochemistry was built into the B-ring by a series of acyclic aldol additions in Steps **A** through **D**. A silyl ketene acetal derivative

a. T. Mukaiyama, I. Shiina, H. Iwadare, M. Saitoh, T. Nishimura, N. Ohkawa, H. Sakoh, K. Nishimura, Y. Tani, M. Hasegawa, K. Yamada, and K. Saitoh, *Chem. Eur. J.*, **5**, 121 (1999).

of methyl α -benzyloxyacetate served as the nucleophile in Steps A and C. The C(10)–C(11) bond is formed in Step C using MgBr_2 to promote the Mukaiyama addition, which forms the correct stereoisomer with 4:1 diastereoselectivity. The B-ring was closed in Step E-3 by a samarium-mediated cyclization, forming the C(3)–C(18) bond.

The C(4)–C(7) segment was added by a cuprate conjugate addition in Step **F**-1. The C-ring was then closed using an intramolecular aldol addition in Step **F**-4. The A-ring was closed by a Ti-mediated reductive coupling between carbonyl groups at C(11) and C(12) in Step **H**-5. The C(11)–C(12) double bond was introduced from the diol by deoxygenation of the thiocarbonate (Steps **I**-6 and **I**-7). The final sequence for conversion to Baccatin III, which began with a copper-mediated allylic oxidation at C(5), also involves an allylic rearrangement of the halide that is catalyzed by CuBr. The exocyclic double bond was then used to introduce the final oxygens needed to perform the oxetane ring closure.

Another Japanese group developed the Baccatin III synthesis shown in Scheme 13.58. The eight-membered B-ring was closed early in the synthesis using a Lewis acid-induced Mukaiyama reaction (Step **B**-1), in which a trimethylsilyl dienol ether served as the nucleophile.

Oxygen was introduced at C(4) and C(7) by a singlet O_2 cycloaddition in Step **C**-1. The peroxide bond was cleaved and the phenylthio group removed by Bu_3SnH in Step **C**-2. The C(19) methyl group was introduced via a cyclopropanation in Step **C**-5, followed by a reduction in Step **D**-1. A Pd-catalyzed cross-coupling reaction was used to introduce a trimethylsilylmethyl group at C(4) via an enol triflate in Step **F**-2. The vinyl silane was then subjected to chlorination in Step **F**-3. The chlorine eventually serves as the leaving group for oxetane ring formation in Step **G**-2.

These syntheses of Baccatin III illustrate the versatility of current methodology for ring closure and functional group interconversions. The Holton, Nicolaou, Danishefsky, and Wender syntheses of Baccatin III employ various cyclic intermediates and take advantage of stereochemical features built into these rings to control subsequent reaction stereochemistry. As a reflection of the numerous oxygens in Baccatin III, each of the syntheses makes use of enolate oxidation, alkene hydroxylation, and related oxidation reactions. These syntheses also provide numerous examples of the selective use of protective groups to achieve distinction between the several hydroxy groups that are present in the intermediates. The Mukaiyama synthesis in Scheme 13.57 is somewhat different in approach in that it uses acyclic intermediates to introduce

several of the stereocenters. Perhaps because of the structure, none of these syntheses is particularly convergent. The Nicolaou, Danishefsky, and Kusama syntheses achieve some convergence by coupling the A-ring and the C-ring and then forming the B-ring. The Holton and Wender syntheses take advantage of available natural substances as starting materials.

13.2.5. Epothilone A

The epothilones are natural products containing a 16-membered lactone ring that are isolated from mycobacteria. Epothilones A–D differ in the presence of the C(12)–C(13) epoxide and in the C(12) methyl group. Although structurally very different from Taxol, they have a similar mechanism of anticancer action and epothilone A and its analogs are of substantial current interest as chemotherapeutic agents.³⁶ Schemes 13.59 to 13.66 summarize eight syntheses of epothilone A. Several syntheses of epothilone B have also been completed.³⁷

Two critical objectives for planning the synthesis of epothilone A are the control of the configuration of the stereocenters and the closure of the 16-membered ring. There are eight stereocenters, including the C(16)–C(17) double bond. As the 16-membered lactone ring is quite flexible, it does not impose strong facial stereoselectivity. Instead, the stereoselective synthesis of epothilone A requires building the correct stereochemistry into acyclic precursors that are cyclized later in the synthesis. The stereocenters at C(3), C(6), C(7), and C(8) are adjacent to a potential aldol connection

a. K. C. Nicolaou, F. Sarabia, S. Ninkovic, and Z. Yang, *Angew. Chem. Int. Ed. Engl.*, **36**, 525 (1997); K. C. Nicolaou, S. Ninkovic, F. Sarabia, D. Vourloumis, Y. He, H. Vallberg, M. R. V. Finlay, and Z. Yang, *J. Am. Chem. Soc.*, **119**, 7974 (1997).

between C(6) and C(7) and are amenable to control by aldol methodology. Introduction of the epoxide by epoxidation requires a *Z*-double bond. Several methods for ring closure have been used, but the two most frequently employed are macrolactonization (see Section 3.4) and alkene metathesis (see Section 8.4).

K. C. Nicolaou's group at Scripps Research Institute developed two synthetic routes to epothilone A. One of the syntheses involves closure of the lactone ring as a late step. Three major fragments were synthesized. The bond connection at C(6)–C(7) was made by an aldol reaction. The C(12)–C(13) bond was formed by a Wittig reaction and later epoxidized. The ring was closed by macrolactonization.

Scheme 13.60. Epothilone A Synthesis by Olefin Metathesis: K. C. Nicolaou and Co-Workers^a

a. Z. Yang, Y. He, D. Vourloumis, H. Vallberg, and K. C. Nicolaou, *Angew. Chem. Int. Ed. Engl.*, **36**, 166 (1997).

This synthesis is shown in Scheme 13.59. Two enantiomerically pure starting materials were brought together by a Wittig reaction in Step C. The aldol addition in Step D was diastereoselective for the *anti* configuration, but gave a 1:1 mixture with the 6*S*, 7*R*-diastereomer. The stereoisomers were separated after Step E-2. The macrolactonization (Step E-4) was accomplished by a mixed anhydride (see Section 3.4.1). The final epoxidation was done using 3-methyl-3-trifluoromethyl dioxirane.

The second synthesis from the Nicolaou group is shown in Scheme 13.60. The disconnections were made at the same bonds as in the synthesis in Scheme 13.59. The C(1)–C(6) segment contains a single stereogenic center, which was established in Step A-1 by enantioselective allylboration. The C(6)–C(7) configuration was established by the aldol addition in Step B. The aldolization was done with the dianion and gave a 2:1 mixture with the 6*S*, 7*R* diastereomer. The two fragments were brought together by esterification in Step D. The synthesis used an olefin metathesis reaction to construct the 16-membered ring (Step E). This reaction gave a 1:4:1 ratio of *Z*:*E* product, which was separated by chromatography.

The olefin metathesis reaction was also a key feature of the synthesis of epothilone A completed by a group at the Technical University in Braunschweig, Germany (Scheme 13.61). This synthesis employs a series of stereoselective additions to create the correct substituent stereochemistry. Two enantiomerically pure starting materials

- a. D. Schinzer, A. Limberg, A. Bauer, O. M. Bohm, and M. Cordes, *Angew. Chem. Int. Ed. Engl.*, **36**, 523 (1997);
 D. Schinzer, A. Bauer, O. M. Bohm, A. Limberg, and M. Cordes, *Chem. Eur. J.*, **5**, 2483 (1999).

were used, containing the C(3) and C(8) stereocenters. Step **B** used a stereoselective aldol addition to bring these two fragments together and to create the stereocenters at C(6) and C(7). The thiazole ring and the C(13)–C(15) fragment were constructed in sequence **C**. The configuration at C(15) was established by enantioselective allylboration in Step **C**-3. The two segments were coupled by esterification at Step **D**, and the ring was closed by olefin metathesis (Step **E**). The metathesis reaction gave a 1.7:1 ratio favoring the *Z*-isomer. The synthesis was completed by deprotection and epoxidation, after which the stereoisomers were separated by chromatography. This group has also completed a synthesis based on a macrolactonization approach.³⁸

Samuel Danishefsky's group at the Sloan Kettering Institute for Cancer Research in New York has also been active in the synthesis of the natural epothilones and biologically active analogs. One of their syntheses also used the olefin metathesis reaction (not shown). The synthesis in Scheme 13.62 used an alternative approach to create the macrocycle, as indicated in the retrosynthetic scheme. The stereochemistry at C(6), C(7), and C(8) was established by a $TiCl_4$ -mediated cyclocondensation (Step **A**). The thiazole-containing side chain was created by reaction sequences **F** and **G**. The

Scheme 13.62. Epothilone A Synthesis by Macroaldol Cyclization: S. J. Danishefsky and Co-Workers^a

a. A. Balog, D. Meng, T. K. Kamenecka, P. Bertinato, D.-S. Su, E. J. Sorensen, and S. J. Danishefsky, *Angew. Chem. Int. Ed. Engl.*, **35**, 2801 (1996); D. Meng, P. Bertinato, A. Balog, D.-S. Su, T. Kamenecka, E. J. Sorensen, and S. J. Danishefsky, *J. Am. Chem. Soc.*, **119**, 10073 (1997).

Z-vinyl iodide was obtained by hydroboration and protonolysis of an iodoalkyne. The two major fragments were coupled by a Suzuki reaction at Steps **H**-1 and **H**-2 between a vinylborane and vinyl iodide to form the C(11)–C(12) bond. The macrocyclization was done by an aldol addition reaction at Step **H**-4. The enolate of the C(2) acetate adds to the C(3) aldehyde, creating the C(2)–C(3) bond and also establishing the configuration at C(3). The final steps involve selective deprotonation and oxidation at C(5), deprotection at C(3) and C(7), and epoxidation.

a. A. Furstner, C. Mathes, and C. W. Lehmann, *Chem. Eur. J.*, **7**, 5299 (2001).

The epothilone A synthesis shown in Scheme 13.63 involves an *alkyne metathesis reaction*. The first subunit was constructed using a Reformatsky-type addition to 3-hydroxypropanonitrile. The configuration at C(3) was established by an enantioselective hydrogenation using (*S*)-(BINAP)RuCl₂ under acidic conditions. A bornane-sultam chiral auxiliary was used to establish the stereochemistry at C(8) by alkylation (Step C-1). The stereochemistry at the C(6)–C(7) bond was established by an aldol addition at Step D. The thiazole segment was constructed from a conjugated enal, which was subjected to enantioselective allylboration using (+)-Ipc₂BCH₂CH=CH₂ in Step F-1. This reaction established the configuration at C(5). A terminal alkyne was then installed by the Corey-Fuchs procedure (see p. 835). The lithium acetylide was methylated in situ using CH₃I. A DMAP-DCCl esterification was then used to couple the two major fragments and set the stage for the alkyne metathesis at Step H. The

catalyst is a molybdenum amide, which is one of a family of catalysts that show good activity in alkyne metathesis. The use of alkyne metathesis avoids the complication of formation of both *Z*- and *E*-isomers, which sometimes occurs in olefin metathesis.

The yield in the metathesis reaction was 80% and was followed by a Lindlar reduction. The synthesis was completed by epoxidation with DMDO.

The synthesis in Scheme 13.64 was carried out by E. Carreira and co-workers at ETH in Zurich, Switzerland. A key step in the synthesis in Scheme 13.64 is a stereoselective cycloaddition using a phosphonyl-substituted nitrile oxide, which was used to form the C(16)–C(17) bond and install the C(15) oxygen.

The C(6)–C(15) segment was synthesized by Steps C-1 and C-2. The stereoselectivity of the cycloaddition reaction between the nitrile oxide and allylic alcohol is the result of a chelated TS involving the Mg alkoxide.³⁹

After the cycloaddition, the thiazole ring was introduced via a Wadsworth-Emmons reaction at Step D, forming the C(17)–C(18) bond.

³⁹. S. Kanemasa, M. Nishiuchi, A. Kamimura, and K. Hori, *J. Am. Chem. Soc.*, **116**, 2324 (1994); S. Fukuda, A. Kanimura, S. Kanemasa, and K. Hori, *Tetrahedron*, **56**, 1637 (2000).

The C(1)–C(6) and C(7)–C(17) fragments were joined by an aldol addition via a lithium enolate (Step F-1), and the ring was closed by a macrolactonization.

The synthesis of epothilone A in Scheme 13.65 features the use of chiral allylic silanes that were obtained by kinetic resolution using *Pseudomonas* AK lipase. The C(5)–C(8) fragment was synthesized by condensing the enantiomerically pure silane with a TBDPS-protected aldehyde in the presence of BF_3 . The adduct was then subjected to a chelation-controlled aldol addition using TiCl_4 , adding C(3) and C(4). After protecting group manipulation and oxidation, the chain was extended by two carbons using a Wittig reaction in Step C-3. The methyl group at C(8) was added by a stereoselective cuprate conjugate addition in Step C-4. The intermediate was then converted to **8** using a DiBAIH reduction under conditions that discriminated between the two ester groups (Step D-1). The more hindered group was reduced to the primary alcohol, leaving the less hindered one at the aldehyde level. This selectivity probably arises as a result of the lesser stability of the more hindered partially reduced intermediate. (See p. 401 to review the mechanism of DiBAIH reduction.)

The aldehyde was then converted to the terminal alkene via a Wittig reaction (Step D-3).

A kinetic resolution was also used to establish the configuration of the thiazole portion. An allylic aldehyde was subjected to kinetic resolution by ester exchange with vinyl acetate in Step E-2 (see Topic 2.2, Part A). The resolved alcohol was protected and subjected to hydroboration, oxidation, and a Wittig reaction to introduce the *Z*-vinyl iodide. The two fragments were coupled using the Suzuki reaction and the final two carbons were installed by another TiCl_4 -mediated silyl ketene acetal addition in sequence H. The stereochemistry at C(3) presented some problems, but use of the silyl ketene acetal of the isopropyl ester provided an 8:1 mixture favoring the desired diastereomer. The isopropyl ester was used to slow competing lactonization of the intermediate. The macrolactonization was done under the Yamaguchi conditions. The synthesis was completed by epoxidation using the peroxyimide acid generated in situ from acetonitrile and hydrogen peroxide.

The synthesis shown in Scheme 13.66 starts with the Sharpless asymmetric epoxidation product of geraniol. The epoxide was opened with inversion of configuration by $\text{NaBH}_3\text{CN}\text{--}\text{BF}_3$. The double bond was cleaved by ozonolysis and converted to the corresponding primary bromide. The terminal alkyne was introduced by alkylation of

a. B. Zhu and J. S. Panek, *Eur. J. Org. Chem.*, 1701 (2001).

sodium acetylide, completing the synthesis of the C(7)–C(13) segment (Steps A-4 to A7). The BF_3 -mediated epoxide ring opening in Step B-2 occurred with inversion of configuration, establishing the configuration at C(15). The Z-stereochemistry at the C(12)–C(13) double bond was established by reduction over a Lindlar catalyst. An EE protecting group was used during the Swern oxidation (Step C-4) but then replaced by a TBDMS group for the Wittig reaction and beyond. The chirality of the C(1)–C(6) segment was established by a kinetic resolution of an epoxide by selective ring opening

a. Z.-Y. Liu, Z.-C. Chen, C.-Z. Yu, R.-F. Wang, R.-Z. Zhang, C.-S. Huang, Z. Yan, D.-R. Cao, J.-B. Sun, and G. Li, *Chem. Eur. J.*, **8**, 3747 (2002).

catalyzed by a chiral salen-Co(III) complex.⁴⁰ The resolved epoxide was converted to an ester by a $\text{Co}_2(\text{CO})_8$ -catalyzed carbonylation in Step E-1. The C(6)–C(7) bond was formed by an aldol reaction of a *dianion* of the intermediate. The product was a 1:1 mixture of diastereomers. After protecting group manipulations, this adduct was cyclized by macrolactonization. The two diastereomers were separated prior to completion of the synthesis by deprotection and epoxidation.

⁴⁰ M. Tokunaga, J. F. Larrow, F. Kakiuchi, and E. N. Jacobsen, *Science*, **277**, 936 (1997).

Although each of the epothilone syntheses has its unique features, there are several recurring themes. Each synthesis uses one or more enantiopure compound as a starting material. All except the Danishefsky synthesis in Scheme 13.62 utilize the ester bond as a major disconnection. Most also use the C(12)–C(13) double bond as a second major disconnection, and several make the synthetic connection by the alkene (or alkyne) metathesis reaction. Others make the C(11)–C(12) disconnection and use a Suzuki coupling reaction in the synthetic sense to form the C(10)–C(11) bond. Wittig reactions figure prominently in the assembly of the thiazole-containing side chain. The configuration of the isolated stereocenter at C(15) is established by use of an enantiopure starting material (Schemes 13–59, 13–62, 13–64, and 13–66), an enantioselective reagent (Schemes 13–60, 13–61, and 13–63), or a kinetic resolution (Scheme 13–65). The stereochemical issues present are in the C(3)–C(8) segment and are addressed mainly by aldol reaction stereoselectivity.

13.2.6. Discodermolide

(+)-Discodermolide is a natural product isolated from a deep-water sponge found in the Caribbean Sea. The compound is probably produced by a symbiotic microorganism and isolation is not currently a practical source of the material. Like Taxol and epothilone A, (+)-discodermolide is a microtubule stabilizing agent with a promising profile of antitumor activity. A significant feature of the discodermolide structure is the three CH₃–OH–CH₃ triads that establish the configuration of nine stereogenic centers. The C(2)–C(4) and C(18)–C(20) triads are *syn*, *anti*, whereas the C(10)–C(12) triad is *anti*, *syn*. Seven syntheses are described here. Recently, major elements of two of these syntheses have been combined to provide sufficient material for Phase I clinical trials of (+)-discodermolide.

The first (+)-discodermolide synthesis was completed by Stuart Schreiber's group at Harvard University and is outlined in Scheme 13.68. This synthesis was carried through for both enantiomers and established the absolute configuration of the natural material. The retrosynthetic plan outlined in Scheme 13.67 emphasizes the stereochemical triads found at C(2)–C(4), C(10)–C(12) and C(18)–C(20) and was designed to use a common chiral starting material. Each of the segments contains one of the stereochemical triads.

The starting material for the synthesis, methyl (*S*)-3-hydroxy-2-methylpropanoate, was converted to the corresponding aldehyde by reduction. The aldehyde was then converted to the diastereomeric homoallylic alcohols **9** and **10** using a chiral crotonylboronate (Scheme 13.68). The stereochemistry at C(5) was established by formation of the phenyldioxane ring by conjugate addition of a hemiacetal intermediate in Step A-3. After oxidation of C(1) to the aldehyde level the compound was rearranged to **11**, which eventually furnished the lactone terminus. The aldehyde group was introduced

Scheme 13.67. Retrosynthetic Analysis of (+)-Discodermolide to Fragments containing Stereotriads^a

a. D. T. Hung, J. B. Nerenberg, and S. L. Schreiber, *J. Am. Chem. Soc.*, **118**, 11054 (1996).

prior to coupling by reductions of the *N*-methyl-*N*-methyl amide by LiAlH_4 (Steps **B**-5 to **B**-7). This fragment was carried through most of the synthesis as the corresponding phenylthio acetal.

The stereoisomeric alcohol **10** was converted to the C(9)–C(15) fragment by a *Z*-selective Wadsworth-Emmons reaction, followed by reduction of the ester group in Steps **C**-1 to **C**-4. The alcohol was protected as the pivalate ester and then converted to a terminal alkyne using dimethyl diazomethylphosphonate. The C(1)–C(7) and C(8)–C(15) fragments were coupled by a Ni-catalyzed Cr(II) reaction in Step **E**. After reduction to the *Z*-alkene, the allylic alcohol was converted to the bromide via a mesylate. This set the stage for coupling with the C(16)–C(24) segment by enolate alkylation. The C(16) methyl group was installed at this point by a second alkylation (Step **H**-2). When the alkylation was carried out with this methyl group already in place, the C(16) epimer of (+)-discodermolide was obtained. The final conversion to (+)-discodermolide was achieved after carbamoylation of the C(19) hydroxy group. This group promoted stereoselective reduction at C(17) using a bulky hydride reducing agent. Deprotection then gave (+)-discodermolide.

The synthesis of (+)-discodermolide in Scheme 13.69 was completed in James Marshall's laboratory at the University of Virginia and applies allenylmetal methodology at key stages. The starting material was *O*-protected (*S*)-3-hydroxy-2-methylpropanal. An enantiopure butynyl mesylate was the other starting material. The $\text{CH}_3\text{-OH-CH}_3$ stereochemical triad was established by addition to the aldehyde using Pd-catalyzed reaction with an allenyl zinc reagent generated from a butenyl

a. D. T. Hung, J. B. Nerenberg, and S. L. Schreiber, *J. Am. Chem. Soc.*, **118**, 11054 (1996).

mesylate (Step A). The adduct was cyclized as a 1,3-dioxane and further elaborated to an aldehyde intermediate. Reduction to an allylic alcohol by Red-Al was followed by Sharpless epoxidation. The epoxide was opened by a second Red-Al reduction. After protecting group manipulation, the aldehyde functional group was obtained by Swern oxidation. (Steps C-1 to C-7). This aldehyde was coupled

Scheme 13.69. Discodermolide Synthesis: J. A. Marshall and Co-Workers^a

a. J. A. Marshall, Z.-H. Lu, and B. A. Johns, *J. Org. Chem.*, **63**, 817 (1998); J. A. Marshall and B. A. Johns, *J. Org. Chem.*, **63**, 7885 (1998).

with a protected alkyne, forming the C(7)–C(8) bond (Step **D**). Reduction with a Lindlar catalyst gave the *Z*-double bond, which provided C(1)–C(13) of the discodermolide skeleton with the correct stereochemistry. A terminal vinyl iodide including C(14) and its methyl substituent was introduced by a Wittig reaction using 1-iodoethylidenetriphenylphosphorane.

a. A. B. Smith, III, B. S. Freeze, M. Xian, and T. Hirose, *Org. Lett.*, **7**, 1825 (2005).

The C(15)–C(24) segment was constructed by addition of a chiral allenylstannane reagent to the starting aldehyde in Step F. The propargyl acetate terminus was reduced by DiBAIH, giving an allylic alcohol that was subjected to Sharpless asymmetric epoxidation. The methyl substituent at C(20) was added by nucleophilic opening of the epoxide with dimethylcyanocuprate. This segment was extended to include the terminal diene unit in G-9 and G-10. The terminal diene unit was

introduced by CrCl_2 -mediated addition in Step **G**-10, followed by base-induced elimination from the β -hydroxysilane.

The two major subunits were coupled by a Suzuki reaction in Step **H**-3. The synthesis was then completed by reductive opening of the 1,3-dioxane ring, oxidation of the terminal alcohol to the carboxylic acid, carbamoylation, deprotection, and lactonization.

The synthesis of discodermolide in Scheme 13.70 was developed by A. B. Smith, III, and co-workers at the University of Pennsylvania. The synthesis shown in the scheme, which is the result of refinement of several previous syntheses from this laboratory, used a common precursor prepared in Steps **A** and **B**. The stereochemistry of the fragments was established by use of oxazolidinone chiral auxiliaries. The boron enolate of *N*-propanoyl-4-benzylloxazolidinone was added to PMP-protected (*S*)-3-hydroxy-2-methylpropanal in Step **A**. The chiral auxiliary was then replaced by an *N*-methoxy-*N*-methylamide in Step **B**. This intermediate was used for the construction of the C(1)–C(8) and C(9)–C(14) segments. The connection between these two fragments was made by a Wittig reaction at Step **H**. The C(15)–C(21) segment was also derived from an oxazolidinone chiral auxiliary, in this case the (*R*)-enantiomer. The configuration at C(20) was established by allylboration (Step **J**-4). The terminal diene was introduced by a Wittig reaction in Step **K**-1. The two major segments were then coupled at the C(14)–C(15) bond by using the Suzuki reaction in Step **L**. The final steps involve deprotection and installation of the carbamoyl group. The overall yield for this version is 9% with a longest linear sequence of 17 steps.

Scheme 13.71 shows the most recent version of a synthesis of (+)-discodermolide developed by Ian Paterson's group at Cambridge University. The synthesis was based on three major subunits and used boron enolate aldol addition reactions to establish the stereochemistry.

a. I. Paterson, G. J. Florence, K. Gerlach, J. P. Scott, and N. Sereinig, *J. Am. Chem. Soc.*, **123**, 9535 (2001); I. Paterson, O. Delgado, G. J. Florence, I. Lyothier, J. P. Scott, and N. Sereinig, *Org. Lett.*, **5**, 35 (2003); I. Paterson and I. Lyothier, *J. Org. Chem.*, **70**, 5494 (2005).

The synthesis of the C(1)–C(6) subunit was based on addition of an enol boronate to 3-benzyloxypropanal through TS-1. Immediate reduction of the chelate is also stereoselective and provides the intermediate **13**. These steps establish the configuration at C(2)–C(5).

The diol was protected and the C-terminal group converted to a methyl ester in sequence **B**. A phosphonate group was installed at C(7) via an acylation reaction in Step **C**-5. Successive oxidations of the primary and deprotected secondary alcohol gave the C(1)–C(8) intermediate.

The C(9)–C(16) subunit was synthesized from the same starting material. The chain was extended by a boron enolate addition to 2-methylpropenal (Step **D**-2). After introduction of a double bond by selenoxide elimination in Step **E**-4, a Claisen rearrangement was used to generate an eight-membered lactone ring (Step **E**-6).

The lactone ring was then opened and the carboxy group converted to a hindered phenolic ester (Step **F**-4), providing the C(9)–C(16) intermediate.

The synthesis of the C(17)–C(24) segment also began with a diastereoselective boron enolate aldol addition. The adduct was protected and converted to an aldehyde in sequence **H**. The terminal diene unit was installed using a γ -silylallyl chromium reagent, which generates a β -hydroxysilane. Peterson elimination using KH then gave the *Z*-diene.

The three fragments were then coupled. The C(16)–C(17) bond was established by addition of the lithium enolate of the aryl ester in the C(9)–C(16) fragment with the aldehyde group of the C(17)–C(24) fragment. The stereochemistry is consistent with the cyclic aldol addition TS. The adduct was immediately reduced to the diol **14** by LiAlH_4 .

The primary hydroxymethyl group at C(16) was deoxygenated via the mesitylenesulfonate. After removal of the PMP protecting group, a sterically demanding oxidant, TEMPO- $\text{PhI}(\text{OAc})_2$ was used to selectively oxidize the primary alcohol group to an aldehyde. The Still-Gennari version of the Wadsworth-Emmons reaction was used to couple with the C(1)–C(8) fragment in Step **L**. This reaction proceeded with 5:1 *Z* : *E* selectivity and led to isolation of the *Z*-product in 73% yield. The PMB protecting group was then removed and the carbamate group introduced at C(19). The remaining protecting groups were then removed and the lactonization completed the synthesis.

The overall yield was about 12% over a longest linear sequence of 23 steps and about 40 steps total. The major disconnections are illustrated below.

The synthesis outlined in Scheme 13.72 was carried out by James Panek's group at Boston University and is based on three key intermediates that were synthesized from two closely related methyl 3-(dimethylphenylsilyl)hex-4-enoates.

The stereochemistry was controlled by Lewis acid-induced addition of these allylic silanes to aldehydes. The reaction of the silane with O-protected (*S*)-3-hydroxy-2-methylpropanal provides **15**. The silane reacted with the benzyl-protected analog to provide **16**.

a. A. Arefolov and J. S. Panek, *J. Am. Chem. Soc.*, **127**, 5596 (2005).

These intermediates were then converted to the fragments **I** and **II**, respectively. Intermediate **15** is protected as a cyclic acetal and then ozonized to give segment **I**. In the synthesis of the **II** fragment the adduct was extended by two Corey-Fuchs sequences with in situ functionalization to provide the alkyne intermediate **II** (Steps **D-2** and **D-9**). Trimethylsilyl and methyl groups were introduced at C(14) and a formyl groups was added at C(8). The fragments **I** and **II** were coupled by boron enolate methodology and a single stereoisomer was obtained in 88% yield (Step **E**).

The coupled fragments were then converted to a vinyl iodide. The key steps were a *Z*-selective Lindlar reduction and iodinolysis of the vinyl silane, which was done using NIS in acetonitrile (sequence **F-1** to **F-11**).

The C(15)–C(24) segment **C** was created by two successive additions of the allylic silane synthons (Steps **G-1** and **H-3**). The unsaturated esters resulting from the additions were subjected to ozonolysis. The terminal diene unit was added using a silyl-substituted allylic boronate and then subjected to base-mediated elimination. The coupling of the **I-II** and **III** segments was done by Suzuki methodology. It was also carried out in somewhat lower yield using a zinc reagent prepared from the vinyl iodide. The synthesis was completed by deprotection and lactonization. There are a total of 42 steps, with the longest linear sequence being 27 steps, in overall 21% yield.

The synthesis of discodermolide in Scheme 13.73 was completed at the University of California, Berkeley by D. C. Myles and co-workers. The synthesis began with a TiCl_4 -mediated cycloaddition that gave a dihydropyrone intermediate that contains the stereochemistry at C(10)–C(12) and the *Z*-configuration at the C(13)–C(14) double bond. Reduction and H^+ -promoted Ferrier rearrangement gave a lactol containing C(9)–C(15) (Steps **B-1** and **B-2**). This lactol was converted to an allylic iodide, providing one of the key intermediates, **II**.

The stereochemistry at C(18)–C(20) was established using an oxazolidinone chiral auxiliary (Step **D-1**). Carbon-16 and its methyl substituent were added by a Grignard addition in Step **D-4**. The C(9)–C(15) and C(16)–C(21) segments were joined by enolate alkylation (Step **E**). Under optimum conditions, a 6:1 preference for the desired stereoisomer at C(16) was achieved. The stereochemistry at C(17) was established by LiAlH_4 reduction in the presence of LiI , with 8:1 stereoselectivity. An iodovinyl group containing C(8) was installed using iodomethylenetriphenylphosphorane, giving a *Z* : *E* isomer ratio of 20:1 (Step **G-2**). The terminal diene unit was installed using a γ -silylallylboronate, followed by base-mediated *syn* elimination (Steps **G-5** and **G-6**). The carbamate group was then installed, completing the synthesis of intermediate **III**.

The synthesis of the C(1)–C(7) fragment began with allylstannylation (Step **H**). The C(1)–C(2) terminus was introduced using the dibutylboron enolate of an oxazolidinone chiral auxiliary. The C(8)–C(24) fragment was added via a $\text{NiCl}_2\text{-CrCl}_2$ coupling. This reaction was improved by inclusion of a chiral *bis*-pyridine ligand. Sequential deprotection and lactonization afforded discodermolide. The overall yield was 1.5% based on a 22-step longest linear sequence.

The synthesis of (+)-discodermolide shown in Scheme 13.74 was developed in the laboratories of the Novartis Pharmaceutical Company and was designed to provide sufficient material for initial clinical trials. The synthesis is largely based on the one

Scheme 13.73. Discodermolide Synthesis: D. C. Myles Co-workers^aa. S. S. Harried, C. P. Lee, G. Yang, T. I. H. Lee, and D. C. Myles, *J. Org. Chem.*, **68**, 6646 (2003).

by A. B. Smith, III, and co-workers (Scheme 13.70), with the final stages being based on the synthesis in Scheme 13.71. The synthesis begins with a single starting material having one stereogenic center and proceeds through Smith's common intermediate **17** to three segments containing the stereochemical triads.

A number of modifications were made to meet scale-up requirements. In the preparation of the common intermediate, LiBH_4 was used in place of LiAlH_4 in Step A-2 and a TEMPO- NaOCl oxidation was used in place of Swern oxidation in Step A-3. Some reactions presented difficulty in the scale-up. For example, the boron enolate aldolization in Step B-1 gave about 50% yield on the 20- to 25-kg scale as opposed to greater than 75% on a 50-g scale. The amide formation in Step B-3 was modified to eliminate the use of trimethylaluminum, and the common intermediate **17** could be prepared on a 30-kg scale using this modified sequence. The synthesis of the C(1)–C(6) segment **V** was done by Steps C-1 to C-5 in 66% yield on the scale of several kg.

The C(9)–C(14) segment **VI** was prepared by Steps D-1 to D-3. The formation of the vinyl iodide in Step D-3 was difficult and proceeded in only 25–30% yield. The C(15)–C(21) segment **VII** was synthesized from the common intermediate **17** by Steps E-1 to E-6. A DDQ oxidation led to formation of a 1,3-dioxane ring in Step E-1. The *N*-methoxy amide was converted to an aldehyde by LiAlH_4 reduction and the chain was extended to include C(14) and C(15) using a boron enolate of an oxazolidinone chiral auxiliary. After reductive removal of the chiral auxiliary, the primary alcohol group was converted to a primary iodide. The overall yield for these steps was about 25%.

The C(9)–C(14) and C(15)–C(21) segments were then coupled using Suzuki methodology (Step F). The terminal diene unit was then introduced in Steps G-1 to G-3. The cyclic acetal was reduced with DIBALH , restoring the PMB protecting group and deprotecting the C(21) hydroxy. This primary alcohol was oxidized to the aldehyde and coupled with an allylic silane using CrCl_2 , as in Scheme 13.69. The chain was then extended by adding C(7) and C(8) using the *Z*-selective Still-Gennari modification of the Wadsworth-Emmons reaction (Step H-3) and the ester was converted to an aldehyde. This permitted the final coupling with the C(1)–C(6) fragment using a boron enolate prepared from $(\text{Ipc})_2\text{BCl}$. The optimized procedure gave the product in 50–55% yield with stereoselectivity of about 4:1. A process for converting the minor diastereomer to the desired product was developed. The final reduction was done with $[(\text{CH}_3)_4\text{N}]^+[\text{BH}(\text{OAc})_3]^-$. Removal of the final silyl protecting group and lactonization gave (+)-discodermolide. The overall synthesis involved 39 steps.

These syntheses of (+)-discodermolide provide examples of the application of several current methods for control of acyclic stereochemistry. They illustrate the use of allylic boronates, allenyl stannanes, oxazolidinone auxiliaries, boron enolates, and allylic silanes to achieve enantioselective formation of key intermediates. Wittig and Suzuki reactions figure prominently in the coupling of key intermediates. Several of the syntheses use β -hydroxy silane elimination to introduce the terminal diene. The discodermolide structure lends itself to a high degree of convergency, and the relationship among the three stereochemical triads permits utilization of common starting materials, which contributes to overall synthetic efficiency. The composite synthesis completed by the Novartis group provides an insight into the logistics of scale-up of a synthesis of this complexity. The synthesis described in Scheme 13.74 produced 60 g of pure (+)-discodermolide. The effort involved about 40 chemists and was carried out over a period of 20 months.

13.3. Solid Phase Synthesis

The syntheses discussed in the previous sections were all carried out in *solution phase* and intermediates were isolated and purified. There is another general approach to multistep synthesis in which the starting material is attached to a solid support. The sequence of synthetic steps is then carried out with the various intermediates remaining attached to the solid support. Called *solid phase synthesis*, this approach has a potential advantage in that excess reagents and by-products can simply be washed away after each step. When the synthesis is complete, the product can be detached from the support. Another potential advantage of solid phase synthesis is that the operations can be automated. A particular sequence for addition of reactants, reagents, and solvents for removal of soluble material can be established. Instruments can then be programmed to carry out these operations.

The most highly developed applications of solid phase methods are in the syntheses of polypeptides and oligonucleotides. These molecules consist of linear sequences of individual amino acids or nucleotides. The connecting bonds are the same for each subunit: amides for polypeptides and phosphate esters for the polynucleotides. The synthesis can be carried out by sequentially adding the amino acids or nucleotides and coupling reagents. The ability to synthesize polypeptides and oligonucleotides of known sequence is of great importance in a number of biological applications. Although these molecules can be synthesized by synthetic manipulations in solution, they are now usually synthesized by solid phase methods, using automated repetitive cycles of deprotection and coupling. Another important application of solid phase synthesis is in combinatorial synthesis, where the goal is to make a large number of related molecules by systematic variation of the individual components.

13.3.1. Solid Phase Polypeptide Synthesis

The techniques for automated solid phase synthesis were first highly developed for polypeptides and the method is abbreviated as *SPPS*. Polypeptide synthesis requires the sequential coupling of the individual amino acids. After each unit is added, it must be deprotected for use in the next coupling step.

Excellent solution methods involving alternative cycles of deprotection and coupling are available for peptide synthesis,⁴¹ and the techniques have been adapted to solid phase synthesis.⁴² The N-protected carboxy terminal amino acid is linked to the solid support, which is usually polystyrene with divinylbenzene cross-linking. The amino group is then deprotected and the second N-protected amino acid is introduced and coupled. The sequence of deprotection and coupling is then continued until the synthesis is complete. Each deprotection and coupling step must go in very high yield. Because of the iterative nature of solid phase synthesis, errors accumulate throughout the process. For the polypeptide to be of high purity, the conversion must be very efficient at each step.

The first version of SPPS to be developed used the *t*-Boc group as the amino-protecting group. *t*-Boc can be cleaved with relatively mild acidic treatment and TFA is usually used. The original coupling reagents utilized for SPPS were carbodiimides. In addition to dicyclohexylcarbodiimide (DCCI), *N,N'*-diisopropylcarbodiimide (DIPCDI) is often used. The mechanism of peptide coupling by carbodiimides was

Giralt, *Chemical Synthesis of Peptides and Proteins*, CRC Press, Boca Raton, FL, 1997.

discussed in Section 3.4. Currently, the optimized versions of the *t*-Boc protocol can provide polypeptides of 60–80 residues in high purity.⁴³ The protocol for using *t*-Boc protection is outlined in Scheme 13.75

A second method that uses the fluorenylmethoxycarboxy (Fmoc) protecting group has been developed.⁴⁴ The Fmoc group is stable to mild acid and to hydrogenation, but it is cleaved by basic reagents via fragmentation triggered by deprotonation at the acidic 9-position of the fluorene ring. The protocol for SPPS using the Fmoc group is shown in Scheme 13.76.

In both the *t*-Boc and Fmoc versions of SPPS, the amino acids with functional groups in the side chain also require protecting groups. These protecting groups are designed to stay in place throughout the synthesis and then are removed when the synthesis is complete. The serine and threonine hydroxyl groups can be protected as benzyl ethers. The ϵ -amino group of lysine can be protected as the trifluoroacetyl derivative or as a sulfonamide derivative. The imidazole nitrogen of histidine can also be protected as a sulfonamide. The indole nitrogen of tryptophan is frequently protected as a formyl derivative. The exact choice of protecting group depends upon the deprotection-coupling sequence being used.

The original version of SPPS attached the carboxy terminal residue directly to the resin as a benzylic ester using chloromethyl groups attached to the polymer. At the present time the attachment is done using “linking groups.” Two of the more common linking groups are shown. These groups have the advantage of permitting

milder conditions for the final removal of the polypeptide from the solid support. The C-terminal amino acid is attached to the hydroxy group of the linker.

In the *t*-Boc protocol, the most common reagent for final removal of the peptide from the solid support is anhydrous hydrogen fluoride. Although this is a hazardous reagent, commercial systems designed for safe handling are available. In the Fmoc protocol milder acidic reagents can be used for cleavage from the resin. The alkoxybenzyl group at the linker can be cleaved by TFA. Often, a scavenger, such as thioanisole, is used to capture the cations formed by cleavage of *t*-Boc protecting groups from side-chain substituents.

At the present time, the coupling is usually done via an activated ester (see Section 3.4). The coupling reagent and one of several *N*-hydroxy heterocycles are first allowed to react to form the activated ester, followed by coupling with the deprotected amino group. The most frequently used compounds are *N*-hydroxysuccinimide, 1-hydroxybenzotriazole (HOBt), and 1-hydroxy-7-azabenzotriazole (HOAt).⁴⁷

Another family of coupling reagents frequently used with the Fmoc method is related to *N*-hydroxybenzotriazole and *N*-hydroxy 7-azabenzotriazole but also incorporates phosphonium or amidinium groups. The latter can exist in either the O-(uronium) or *N*-(guanidinium) forms.⁴⁸ Both can effect coupling. The former are more reactive but isomerize to the latter. Which form is present depends on the protocol of preparation, including the amine used and the time before addition of the carboxylic acid.⁴⁹ The

phosphonium coupling reagents are believed to form acyloxyphosphonium species that can then be converted to the active ester incorporating the *N*-hydroxy heterocycle.⁵⁰

The structures and abbreviations of these reagents are given in Scheme 13.77.

The development of highly efficient protection-deprotection and coupling schemes has made the synthesis of polypeptides derived from the standard amino acids a highly efficient process. Additional challenges can come into play when other amino acids are involved. The HATU reagent, for example, has been applied to *N*-methyl amino acids, as in the case of cyclosporin A, an undecapeptide that is important in preventing transplant rejection. Seven of eleven amino acids are *N*-methylated. The synthesis of cyclosporin analogs has been completed by both solution and solid phase methods. Scheme 13.78 summarizes this synthesis. Fmoc protecting groups were used. Unlike the case of normal amino acids, quantitative coupling was not achieved, even when the coupling cycle was repeated twice for each step. Therefore, after each coupling cycle, a *capping step* using acetic anhydride was done to prevent carrying unextended material to the next phase. The final macrocyclization was done using propylphosphonic anhydride and DMAP, a reaction that presumably proceeds through a mixed phosphonic anhydride.⁵¹

13.3.2. Solid Phase Synthesis of Oligonucleotides

Synthetic oligonucleotides are very important tools in the study and manipulation of DNA, including such techniques as site-directed mutagenesis and DNA amplification by the polymerase chain reaction. The techniques for chemical synthesis of oligonucleotides are highly developed. Very efficient automated methodologies based on solid phase synthesis are used extensively in fields that depend on the availability of defined DNA sequences.⁵²

The construction of oligonucleotides proceeds from the four nucleotides by formation of a new phosphorus oxygen bond. The potentially interfering nucleophilic sites on the nucleotide bases are protected. The benzoyl group is usually used for the 6-amino group of adenosine and the 4-amino group of cytidine, whereas the *i*-butyryl group is used for the 2-amino group of guanosine. These amides are cleaved by ammonia after the synthesis is completed. The nucleotides are protected at the 5'-hydroxy group as ethers, usually with the 4,4'-dimethoxytrityl (DMT) group.

In the early solution phase syntheses of oligonucleotides, coupling of phosphate diesters was used. A mixed 3'-ester with one aryl substituent, usually *o*-chlorophenyl, was coupled with a deprotected 5'-OH nucleotide. The coupling reagents were sulfonyl halides, particularly 2,4,6-tri-*i*-propylbenzenesulfonyl chloride,⁵³ and the reactions proceeded by formation of reactive sulfonate esters. Coupling conditions

⁵³ C. B. Reese, *Tetrahedron*, **34**, 3143 (1978).

have subsequently been improved and a particularly effective coupling reagent is 1-mesitylenesulfonyl-3-nitrotriazole (MSNT).⁵⁴

Current solid phase synthesis of oligonucleotides relies on coupling at the phosphite oxidation level. The individual nucleotides are introduced as phosphoramidites and the technique is called the *phosphoramidite method*.⁵⁵ The *N,N*-diisopropyl phosphoramidites are usually used. The third phosphorus substituent is methoxy or 2-cyanoethoxy. The cyanoethyl group is easily removed by mild base (β -elimination) after completion of the synthesis. The coupling is accomplished by tetrazole, which displaces the amine substituent to form a reactive phosphite that undergoes coupling. After coupling, the phosphorus is oxidized to the phosphoryl level by iodine or another oxidant. The most commonly used protecting group for the 5'-OH is the 4,4'-dimethoxytrityl group (DMT), which is removed by mild acid. The typical cycle of deprotection, coupling, and oxidation is outlined in Scheme 13.79. One feature of oligonucleotide synthesis is the use of a *capping step*, an acetylation that follows coupling, the purpose of which is to permanently block any 5'-OH groups that were not successfully coupled. This prevents the addition of a nucleotide at the site in the succeeding cycle, terminates the further growth of this particular oligonucleotide, and avoids the synthesis of oligonucleotides with single-base deletions. The capped oligomers are removed in the final purification.

Silica or porous glass is usually used as the solid phase in oligonucleotide synthesis. The support is functionalized through an amino group attached to the silica surface. There is a secondary linkage through a succinate ester to the terminal 3'-OH group.

Although use of automated oligonucleotide synthesis is widespread, work continues on the optimization of protecting groups, coupling conditions, and deprotection methods, as well as on the automated devices.⁵⁶

13.4. Combinatorial Synthesis

Over the past decade the techniques of *combinatorial synthesis* have received much attention. Solid phase synthesis of polypeptides and oligonucleotides are especially adaptable to combinatorial synthesis, but the method is not limited to these fields. The goal of combinatorial synthesis is to prepare a large number of related

molecules by carrying out a synthetic sequence with several closely related starting materials and reactants. For example, if a linear three-step sequence is done with eight related reactants at each step, a total of 4096 different products are obtained. The product of each step is split into equal portions for the next series of reactions.

The objective of traditional multistep synthesis is the preparation of a single pure compound, but combinatorial synthesis is designed to make many related molecules.⁵⁷ The purpose is often to have a large collection (library) of compounds for evaluation of biological activity. A goal of combinatorial synthesis is *structural diversity*, that is, systematic variation in subunits and substituents so as to explore the effect of a range of structural entities. In this section, we consider examples of the application of combinatorial methods to several kinds of compounds.

One approach to combinatorial synthesis is to carry out a series of conventional reactions in parallel with one another. For example, a matrix of six starting materials, each treated with eight different reactants will generate 48 reaction products. Splitting each reaction mixture and using a different reactant for each portion can further expand the number of final compounds. However, relatively little savings in effort is achieved by running the reactions in parallel, since each product must be separately isolated and purified. The reaction sequence below was used to create a 48-component library by reacting six amines with each of eight epoxides. Several specific approaches were used to improve the purity of the product and maximize the efficiency of the process. First, the amines were monosilylated to minimize the potential for interference from dialkylation of the amine. The purification process was also chosen to improve efficiency. Since the desired products are basic, they are retained by acidic ion exchange resins. The products were absorbed on the resin and nonbasic impurities were washed out, followed by elution of the products by methanolic ammonia.⁵⁸

A considerable improvement in efficiency can be achieved by solid phase synthesis.⁵⁹ The first reactant is attached to a solid support through a linker group, as was described for polypeptide and oligonucleotide synthesis. The individual reaction steps are then conducted on the polymer-bound material. Use of solid phase methodology has several advantages. Excess reagents can be used to drive individual steps to completion and obtain high yields. The purification after each step is also simplified, since excess reagents and by-products are simply rinsed from the solid support. The process can be automated, greatly reducing the manual effort required.

When solid phase synthesis is combined with sample splitting, there is a particularly useful outcome.⁶⁰ The solid support can be used in the form of small beads, and

the starting point is a collection of beads, each with one initial starting material. After each reaction step the beads are recombined and divided again. As the collection of beads is split and recombined during the combinatorial synthesis, each bead acquires a particular compound, depending on its history of exposure to the reagents, *but every bead in a particular split has the same compound, since their reaction histories are identical*. Figure 13.1 illustrates this approach for three steps, each using three different reactants. However, in the end all of the beads are together and there must be some means of establishing the identity of the compound attached to any particular bead. In some cases it is possible to detect compounds with the desired property while they are still attached to the bead. This is true for some assays of biological or catalytic activity that can be performed under heterogeneous conditions.

Another approach is to tag the beads with identifying markers that encode the sequence of reactants and thus the structure of the product attached to a particular bead.⁶¹ One method of coding involves attachment of a chemically identifiable tag,

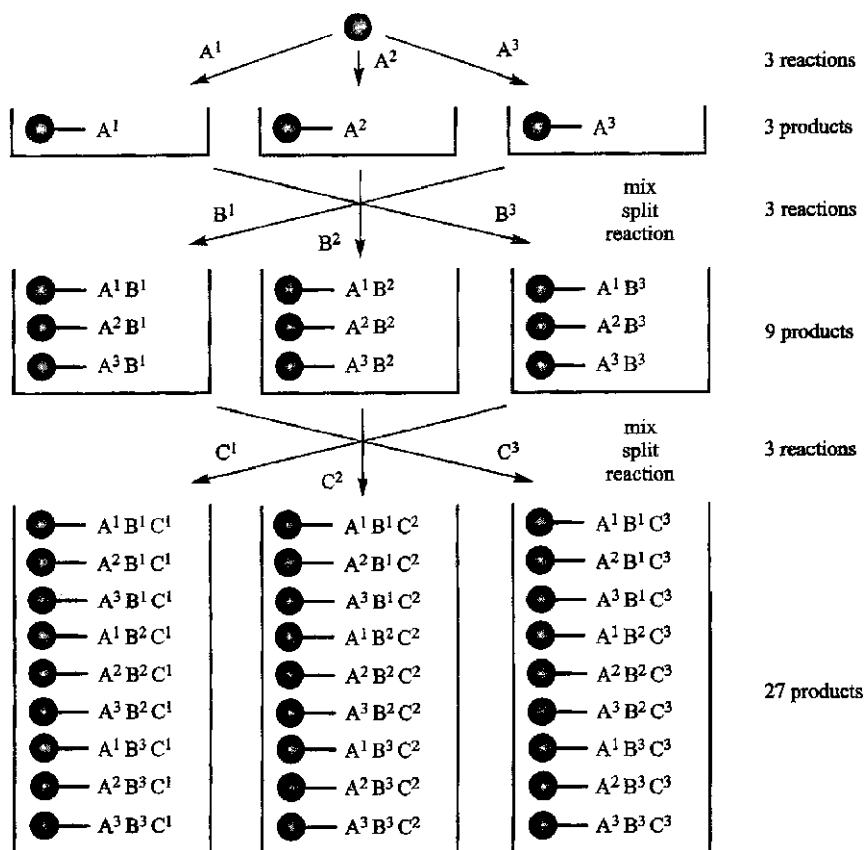

Fig. 13.1. Splitting method for combinatorial synthesis on solid support. Reproduced from F. Balkenhohl, C. von dem Bussche-Huennefeld, A. Lansky, and C. Zechel, *Angew. Chem. Int. Ed. Engl.*, 35, 2288 (1996), by permission of Wiley-VCH.

Fig. 13.2. Use of chemical tags to encode the sequence in a combinatorial synthesis on a solid support. Reproduced from W. C. Still, *Acc. Chem. Res.*, **29**, 155 (1996), by permission of the American Chemical Society.

as illustrated in Figure 13.2.⁶² After each combinatorial step, a different chemical tag is applied to each of the splits before they are recombined. The tags used for this approach are a series of chlorinated aromatic ethers that can be detected and identified by mass spectrometry. The tags are attached to the polymer support by a Rh-catalyzed carbenoid insertion reaction. Detachment is done by oxidizing the methoxyphenyl linker with CAN. Any bead that shows interesting biological activity can then be identified by analyzing the code provided by the chemical tags for that particular bead.

Combinatorial approaches can be applied to the synthesis of any type of molecule that can be built up from a sequence of individual components, for example, in reactions forming heterocyclic rings.⁶³ The equations below represent an approach to preparing differentially substituted indoles.

Ref. 64

There is nothing to prevent incorporation of additional diversity by continuing to build on a side chain at one of the substituent sites.

Another kind of combinatorial synthesis can be applied to reactions that assemble the product from several components in a single step, a *multicomponent reaction*. A particularly interesting four-component reaction is the *Ugi reaction*, which generates dipeptides from an isocyanide, an aldehyde, an amine, and a carboxylic acid.

For example, use of 10 different isocyanides and amines, along with 40 different aldehydes and carboxylic acids has the potential to generate 160,000 different dipeptide analogs.⁶⁵ This system was explored by synthesizing arbitrarily chosen sets of 20 compounds that were synthesized in parallel. The biological assay data from these 20 combinations were then used to select the next 20 combinations for synthesis. The synthesis-assay-selection process was repeated 20 times. At the end of this process the average inhibitory concentration of the set of 20 products had been decreased from 1 mM to less than 1 μM.

A library of over 3000 spirooxindoles was created based on a sequence of four reactions.⁶⁶ The synthetic sequence is based on the total synthesis of a natural product called (–)-spirotryprostatin B.⁶⁷ A morpholinone chiral auxiliary, aldehyde, and an oxindole condense to give the ring system. Substituents were then added by replacement of the iodine by one of several terminal alkynes. Simultaneous deprotection occurred at the allyl ester. These carboxylic acids were converted to amides using a variety of amines and coupling with PyBOP. The final reaction in the sequence was acylation of the oxindole nitrogen. At each stage in the library creation, certain alkynes or amines reacted poorly and were excluded from the library, which was eventually derived from eight alkynes, twelve amines, and four acylation reagents. As outlined in Scheme 13.80, this synthesis has the potential to prepare 3104 different

compounds, including those lacking a particular substituent (skip) (4 aldehydes \times 2 morpholines \times 1 oxindole) = 8 core structures \times (1 + 8 \times 12) \times 4 = 3104 different compounds. A version of the chemical tagging method was used for coding the beads.⁶⁸ Analysis of a sample of the beads indicated that at least 82% of them contained the desired compound in greater than 80% purity.

The epothilone synthesis in Scheme 13.59 (p. 1221) has been used as the basis for a combinatorial approach to epothilone analogs.⁶⁹ The acyclic precursors were

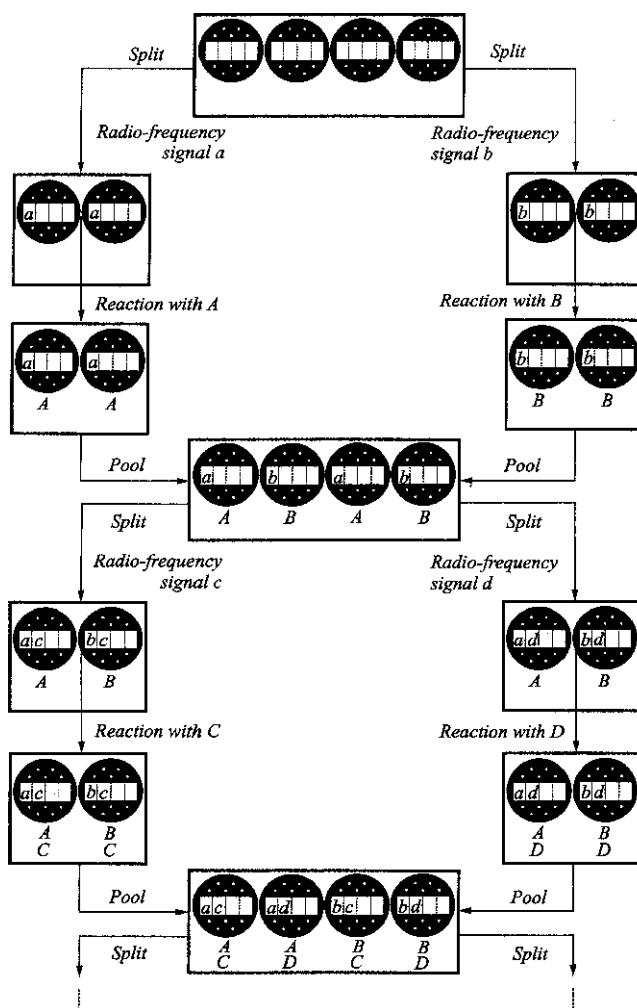

Fig. 13.3. Radio-frequency tagging of microreactors for combinatorial synthesis on a solid support. Reproduced from K. C. Nicolaou, X.-Y. Xiao, Z. Parandoosh, A. Senyei, and M. P. Nova, *Angew. Chem. Int. Ed. Engl.*, **34**, 2289 (1995), by permission of Wiley-VCH.

⁶⁹ K. C. Nicolaou, N. Wissinger, J. Pastor, S. Ninkovic, F. Sarabia, Y. He, D. Vourloumis, S. Yang, T. Li, P. Giannakakou, and E. Hamel, *Nature*, **387**, 268 (1997); K. C. Nicolaou, D. Vourloumis, T.

synthesized and attached to a solid support resin by Steps **A** and **B** in Scheme 13.81. The cyclization and disconnection from the resin was then done by the olefin metathesis reaction in Step **F**. The aldol condensation in Step **D** was not highly stereoselective. Similarly, olefin metathesis gave a mixture of *E*- and *Z*-stereoisomers, so the product of each combinatorial sequence was a mixture of four isomers. These were separated by thin-layer chromatography prior to bioassay. In this project, reactants **A** (three variations), **B** (three variations), and **C** (five variations) were used, generating 45 possible combinations. The stereoisomeric products increase this to 180 (45×4).

In this study a nonchemical means of encoding the identity of each compound was used. The original polymer-bound reagent was placed in a porous microreactor that is equipped with a radiofrequency device that can be used for identification.⁷⁰ The porous microreactors permit reagents to diffuse into the polymer-bound reactants, but the polymer cannot diffuse out. At each split, the individual microreactors are coded to identify the reagent that is used. When the synthesis is complete, the sequence of signals recorded in the radiofrequency device identifies the product that has been assembled in that particular reactor. Figure 13.3 illustrates the principle of this coding method.

Problems

(References for these problems will be found on page 1292.)

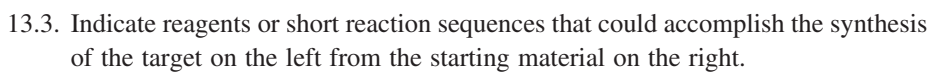

- 13.1. Show how synthetic equivalent groups could be used to carry out each of the following transformations:

13.2. Indicate a reagent or short synthetic sequence that would accomplish each of the following transformations:

13.4. As they are available from natural sources in enantiomerically pure form, carbohydrates are useful starting materials for syntheses of enantiomerically pure compounds. However, the multiple hydroxy groups require versatile methods for selective protection, reaction, and deprotection. Show how appropriate manipulation of protecting groups and/or selective reagents could be used to effect the following transformations.

13.5. Several synthetic transformations that are parts of total syntheses of natural products are summarized by retrosynthetic outlines. For each retrosynthetic transform suggest a reagent or short reaction sequence that could accomplish the forward synthetic conversion. The proposed route should be diastereoselective but need not be enantioselective.

13.6. Diels-Alder reactions are attractive for synthetic application because of the predictable regio- and stereochemistry. There are, however, limitations on the types of compounds that can serve as dienophiles or dienes. As a result, the idea of synthetic equivalence has been exploited by development of dienophiles and dienes that meet the reactivity requirements of the Diels-Alder reaction and can then be converted to the desired structure. For each of the dienophiles and dienes given below, suggest a Diels-Alder reaction and subsequent transformation(s) that would give a product not directly attainable by a Diels-Alder reaction. Give the structure of the diene or dienophile “synthetic equivalent” and indicate why the direct Diels-Alder reaction is not possible.

Dienophiles

Dienes

13.7. One approach to the synthesis of enantiomerically pure compounds is to start with an available enantiomerically pure substance and effect the synthesis by a series of enantiospecific reactions. Devise a sequence of reactions that would be appropriate for the following syntheses based on enantiomerically pure starting materials.

13.8. Several syntheses of terpenoids are outlined in retrosynthetic form. Suggest a reagent or short reaction sequence that could accomplish each lettered transformation in the synthetic direction. The structures refer to racemic material.

- 13.9 Use retrosynthetic analysis to suggest syntheses of the following compounds. Develop at least three outline schemes. Discuss the relative merits of the schemes and develop a fully elaborated synthetic plan for the most promising retrosynthetic scheme.

seychellene

brefeldin A

pentalenolactone E

- 13.10. Suggest a method for diastereoselective synthesis of the following compounds:

- 13.11. Devise a route that could be used for synthesis of the desired compound in high enantiomeric purity from the suggested starting material.

13.12. Select a reagent that will achieve the following syntheses with high enantioselectivity.

13.13. The following reactions use chiral auxiliaries to achieve enantioselectivity. By consideration of possible TSs, predict the absolute configuration of the major product of each reaction.

- 13.14. The macrolide carbonolide B contains six stereogenic centers at sp^3 carbons. Devise a strategy for synthesis of carbonolide B and in particular for establishing the stereochemistry of the C(1)–C(8) segment of the molecule.

carbonolide B

- 13.15. 4-(Acylamino)-substituted carboxylate esters and amides can be alkylated with good *anti*-2,4 stereoselectivity using two equivalents of a strong base. The stereoselectivity is independent of the steric bulk of the remainder of the carboxylate structure. Propose a TS that is consistent with these observations.

- 13.16. Using as a designation of a “step” each numbered reagent or reagent combination in Schemes 13.54 to 13.59 for the synthesis of the Taxol precursors shown there, outline the syntheses in terms of convergence and determine the longest linear sequence (as on p. 1166). In general, these Taxol syntheses are quite linear in character. Is there a structural reason for this tendency toward linearity?

Index

- Acetals as
 - electrophiles in
 - allyl silane addition, 820–821
 - Mukaiyama aldol reaction, 85–86
 - protective groups for
 - alcohols, 258–262
 - carbonyl compounds, 272–275
 - diols, 266–267
- Acrylic acid derivatives
 - α -amido, hydrogenation of
 - computational model for, 380–382
 - enantioselective, 380, 384
 - enantioselective hydrogenation, 380
 - examples, 385–386
- Acyl anion equivalents, 1167–1169
- Acyl chlorides
 - α -halogenation, 331
 - reaction with
 - organocadmium compounds, 661–662
 - organomagnesium compounds, 637–638
 - organozinc compounds, 661
 - silanes, 828–829
 - synthesis using
 - oxalyl chloride, 243
 - triphenylphosphine, carbon tetrachloride, 244
- Acyl iminium ions, 145–146, 199, 828–829
- Acylation of
 - alcohols, 243–252
 - by acyl halides, 244
 - by acyl imidazolides, 246–247
 - by pyridine-2-thiol esters, 248
 - catalysis by DMAP, 244
 - Lewis acid catalysts for, 245–246
 - using 3-chloroisoxazolium salts, 247
 - using 2-chloropyridinium salts, 247
 - using DCCI, 247
 - alkenes, 881–883
 - intramolecular, 882–883
 - amines, 252–257
 - carbon nucleophiles, 148–149
 - enolates, 150–157
 - ester condensation, 149–157
 - malonate magnesium salts, 152
 - silanes, ketones from, 828–829
- Acylium ions
 - in Friedel-Crafts reaction, 1019
 - reaction with alkenes, 881–883
- Acyloin condensation, 450
 - mechanism, 450
- Alcohols
 - acylation of, 243–252
 - by acyl halides, 246
 - by acyl imidazolides, 246–247
 - by Fischer esterification, 252
 - by pyridine-2-thiol esters, 248
 - catalysis by DMAP, 244
 - Lewis acid catalysts for, 242
 - using 3-chloroisoxazolium salts, 247
 - using 2-chloropyridinium salts, 247
 - using DCCI, 247
 - allylic
 - epoxidation of, 1082–1088
 - synthesis
 - from aldehydes and allylic boron compounds, 797–809
 - from aldehydes and allylic silanes, 815–830
 - from alkenes and selenium dioxide, 1124–1126
 - from alkenes and singlet oxygen, 1117–1124
 - from epoxides by base-catalyzed ring opening, 1114–1116

Alcohols (*Cont.*)

- from sulfoxides by [2,3]-sigmatropic rearrangement, 581
- by Wittig reaction, 162
- β -amino, from epoxides, 1107
- β -azido, from epoxides, 1107
- conversion to halides, 217–223
 - examples, 221
 - triphenylphosphine as co-reagent in, 219–221
- conversion to ethers, 227
- conversion to sulfonate esters, 216
- β -cyano, from epoxides, 1106–1107
- enantioselective synthesis
 - by hydroboration-oxidation, 351
 - by reduction of ketones, 415–422
- inversion of configuration by Mitsunobu reaction, 228
- oxidation 1063–1074
 - chromium dioxide, 1068
 - chromium (VI) reagents, 1063–1069
 - Dess–Martin reagent, 1072–1073
 - dimethyl sulfoxide, 1070–1072
 - manganese dioxide, 1067–1068, 1069
 - oxoammonium ions, 1074
 - potassium ferrate, 1068
 - Swern, 1070
- protective groups for, 258–267
 - acetals as, 258–262
 - allyl, 264
 - allyloxycarbonyl, 267
 - benzyl, 262–263
 - t*-butyl, 262
 - t*-butyldimethylsilyl, 264
 - dimethoxybenzyl, 263
 - 2,4-dimethoxytriphenylmethyl, 262
 - ethers as, 262–264
 - 1-ethoxyethyl, 260
 - 2-methoxyethoxymethyl, 260
 - 2-methoxypropyl, 259–260
 - methoxymethyl, 260
 - p*-methoxyphenyl, 263
 - p*-methoxytriphenylmethyl, 262
 - methylthiomethyl, 260
 - table of, 267
 - tetrahydropyranyl, 260
 - trichloroethyloxycarbonyl, 265
 - triisopropylsilyl, 264–265
 - trimethylsilyl, 264
 - 2-trimethylsilylethoxymethyl, 261
 - triphenylmethyl, 262
 - triphenylsilyl, 265
- reductive deoxygenation via thiono esters, 433
 - examples, 434
- synthesis from
 - aldehydes and organometallic reagents, 638
 - alkenes by hydroboration-oxidation, 344–347, 351

- alkenes by oxymercuration-reduction, 294–298
- boranes by carbonylation, 786–787
- epoxides by reduction, 1109–1110
- esters and organomagnesium compounds, 637
- ketones and organometallic reagents, 638
- ketones by reduction, 407–422

unsaturated

- halocyclization of, 317–318

Aldehydes

- aldol reactions of, 65–78
- aromatic
 - reduction by silanes, 425
 - synthesis by formylation, 1024
- enolates, alkylation of, 31
- oxidation
 - manganese dioxide, 1132
- reactions with
 - alkynyl boranes, 805
 - allylic boron compounds, 797–809
 - allylic silanes, 815–827
 - allenyl tin compounds, 850–851
 - allylic tin compounds, 834–849
 - organomagnesium compounds, 638
 - organozinc reagents, 653–654
- silanes from, 836
- stereoselectivity of, in aldol reactions, 86–101
- synthesis from
 - alcohols by oxidation, 1063–1073
 - alkenes by hydroformylation, 759–760
 - boranes by carbonylation, 786–787
 - formamides and organomagnesium reagents, 638
 - nitriles by partial reduction, 402–403
 - esters, by partial reduction, 401–403
 - N*-methoxy-*N*-methylamides, 402
 - triethyl orthoformate and organomagnesium reagents, 638–639

Alder rule, 478

Aldol reaction

- of *N*-acylthiazoline-2-thiones, 81
- boron enolates in, 71–73
 - chiral, 117–119
- chiral auxiliaries for, 114–119
- chiral catalysts for, 125–133
- cyclic transition structure for, 67–68
- directed 65–67
 - examples, 66
- double stereodifferentiation in, 108–114
 - examples, 111–114
- enantioselective catalysts for, 125–133
 - examples, 133
- enolate equivalents in, 65, 82–86
- ester enolates in, 78–81
- generalized 64–65
- intramolecular, 134–139
 - examples, 135–136
 - in longifolene synthesis, 1189
 - Robinson annulation as, 134–139

- ketone enolates in 67–69
 stereoselectivity of, 68–69
 kinetic versus thermodynamic control, 64–65, 71
 macrocyclization by in epothilone A
 synthesis, 1224
 mechanism, 64–65
 Mukaiyama aldol reaction, 82–86
 stereoselectivity of, 65–78, 93–101
 polar substituent effects in, 97, 105
 stereoselectivity of, 86–134
 chelation effects in, 92–96, 102–105
 control by aldehyde, 87–101
 control by enolate, 101–108
 Felkin model for, 90
- Alkenes**
 addition of trifluoroacetic acid, 294
 addition reactions with hydrogen halides,
 290–293
 carbocation rearrangements during, 291
 stereochemistry of, 291–293
 allylic oxidation, 1116–1126
 chromium reagents, 1116–1117
 arylation
 Meerwein arylation, 1035
 palladium-catalyzed, 715–720
 aziridination of, 947
 carboalumination, 354–355
 [2+2]cycloaddition
 examples, 543
 intramolecular, 540–541
 photocycloadditions, 544–548
 with carbonyl compounds, 548–551
 with ketenes, 539–542
 dihydroxylation, 1074–1081
 computational model for, 1078–1079
 co-oxidants for, 1076
 enantioselective, 1076–1078
 examples, 1080
 diimide, reduction by, 388–390
 examples, 389–390
 electrophilic cyclization of, 310–328
 epoxidation, 1091–1103
 computational model, 1092
 by dioxiranes, 1097–1103
 enantioselective by manganese diimines, 1088
 by hydrogen peroxide, 1097
 hydroxy directing effect, 1093, 1095
 by peroxycarboxylic acids, 1091–1096
 by peroxyimidic acids, 1095–1097
 torsional effect on, 1093
 fluorination of, 303–304
 halogenation of, 298–301
 hydration of, 293
 hydroalumination, 353–355
 hydroboration, 337–344
 enantioselective, 347–351
 by halo boranes, 330
 metal catalyzed, 341–342
 regioselectivity of, 337–338
 stereochemistry of, 339
 thermal reversibility of, 342–344
- hydrocarbonylation
 palladium-catalyzed, 749–750
 hydroformylation, 368–387
 hydrogenation, 759–760
 metathesis reactions, 761–766
 catalysts for, 762
 examples, 766
 mechanism, 764
 oxidation
 allylic, 1116–1117
 dihydroxylation, 1074–1081
 palladium-catalyzed, 709–712
 singlet oxygen, 1117–1124
 selenium dioxide, 1124–1126
 oxymercuration, 294–298
 ozonolysis, 1129–1131
 examples, 1130
 palladium-catalyzed arylation, 715–724
 radicals addition, 959–966
 allylic stannanes, 965
 allylic silanes, 965
 examples, 964–965
 mechanism, 960
 substituent effects, 960
 reactions with
 acylium ions, 881–883
 carbenes, 906–908, 916–934
 selenenylation of, 308–310
 sulfenylation of, 307–310
 synthesis from
 alkynes by addition of organocopper
 reagents, 697
 alkynes by partial hydrogenation, 387
 amine oxides by thermal elimination, 597–598
 borane derivatives, stereoselective, 795–797
 carbonyl compounds by olefination reactions,
 157–176, 750
 carbonyl compounds by reductive coupling,
 444–452
 vic-diols by reductive elimination, 458–460
 α -halo sulfones by Ramberg-Bäcklund
 reaction, 895–897
 ketones by Shapiro reaction, 454–456
 α -silyl carbanions by Peterson reaction,
 171–174
 sulfones by Julia reaction, 174–176
 Wittig reaction, 157–164
 xanthates by thermal elimination, 603
- Alkylation**
 of carbon nucleophiles, 21–31
 enamines, 46–48
 enantioselective, 41–45
 imine anions, 48–54
 intramolecular, 36–40
 hydrazones, 53–55
 stereoselectivity, of, 24–29, 32–33
 tandem with Birch reduction, 437

- Alkylation (*Contd.*)
tandem with conjugate addition, 189–190
torsional effect in, 27–28
Friedel-Crafts, 1014–1016
- Alkoxyphosphonium ions
as intermediates in nucleophilic substitution, 219–221
- Alkynes
alkenyl
synthesis by cross-coupling, 734–735
chlorination, 335–336
hydroalumination, 357
hydroboration, 352
hydrogen halide addition, 334–335
hydrogenation, partial, 387
hydrozirconation, 356–357
mercury-catalyzed hydration, 335–336
metathesis reaction with alkenes, 764–765
in epothilone A synthesis, 1225
oxidation
potassium permanganate, 1074
ruthenium dioxide, 1075
palladium-catalyzed coupling, 726–728
reactions with
organocopper-magnesium organometallic reagents, 695–697
organotin hydrides, 833–834
reduction by
dissolving metals, 439
LiAlH₄, 423–425
synthesis from
boranes by homologation, 796–797
- Allene
addition reactions, 333–334
protonation, 333–334
synthesis
from cyclopropylenes, 941
- Allylboration, 799–809; *see also* Aldehydes,
reaction with, allylic boranes
computational model for, 801–802
enantioselective, 799, 804–805
examples, 806–807
Lewis acid catalysis of, 802
stereoselectivity, 798–799, 805
- Allyloxycarbonyl
amine protecting group, 268–269
- Alpine-Hydride®, *see* lithium
B-isopinocampheyl-9-
borabicyclo[3.3.1]nonane hydride
- Amides
N-alkylation of, 230
N-allyl enolates
[3,3]-sigmatropic rearrangement of, 578
O-alkylation of, 230
N-bromo, rearrangement of, 949–950
N-iodo, radical reaction of, 990
lithiation of, 631
- N-methoxy-N-methyl
acylation of enolates by, 154
ketones from, 645
reduction of, 401
primary, from nitriles, 256
partial reduction by DiBAIH, 264
protective groups for
dimethoxyphenyl, 271
4-methoxyphenyl, 271
oxidative rearrangement of, 949, 952
reactions with
organocerium compounds, 666
reduction by
alane, 405
borane, 400, 404–405
lithium aluminum hydride, 398
synthesis of, 252–257
coupling reagents for, 253–254, 1248–1249
from ketones by Schmidt reaction, 950–951
oximes by Beckmann rearrangement, 951
Schotten-Bauman conditions for, 252
- thiono
reduction of, 405
[3,3]-sigmatropic rearrangement of, 579
- α,β-unsaturated
conjugate addition reactions of, 197
γ,δ-unsaturated from O-allyl ketene amination, 576–577
- unsaturated
halocyclization of, 320
mercurocyclization, 326
- Amine oxides
N-allyl, [3,3]-sigmatropic rearrangement of, 582
thermal elimination reactions of, 597–598, 602
- Amines
acylation of, 252–258, 1248–1249
arylation
copper-catalyzed, 1043–1044
palladium-catalyzed, 1047
catalysts for Knoevenagel reactions, 147–148
N-chloro, radical reaction of, 990
enantioselective synthesis
by hydroboration-amination, 351
protective groups for, 267–272
allyloxycarbonyl, 268–269
benzyl, 269
benzyloxycarbonyl, 268, 396
fluorenylmethoxycarbonyl 1247
2-nitrobenzyl, 269
4-pentenyl, 271
phthalimides, 270
t-butoxycarbonyl, 268, 1246
sulfonamides, 271
trichloroethoxycarbonyl, 268
trifluoroacetyl, 270
table of, 272
synthesis by
Curtius rearrangement, 947–948
Gabriel method, 229–230

- Hofmann rearrangement, 949
hydroboration-amination, 346, 351
organocerium addition to hydrazones, 666
reduction of amides, 398, 400, 404–405
reductive amination, 403–404
- Amino acids
synthesis by
amidocarbonylation of aldehydes, 754
enantioselective hydrogenation, 380, 384
(*R*)-*N*-amino-2-methoxymethylpyrrolidine (RAMP), 53
(*S*)-*N*-amino-2-methoxymethylpyrrolidine (SAMP), 53
- Ammonium ylides
N-allyl, [2,3]-sigmatropic rearrangement of, 584–585
examples, 586
formation using diazo compounds, 584–585
- Antisynthetic transforms, 1164
- Aromatic compounds
biaryls, synthesis of
copper-catalyzed, 703–705
nickel-catalyzed, 755–756, 758–759
chromium tricarbonyl complexes, 769–770
- Aromatic substitution, *see also* halogenation,
Nitration aromatic
Birch reduction, 436–438
chloromethylation, 1023
diazonium ion intermediates for, 1003, 1027–1035
electrophilic, 1003, 1004–1027
formylation, 1024
Friedel-Crafts acylation, 1017–1023
Friedel-Crafts alkylation, 1014–1017
halogenation, 1008–1014
mercuration, 1026
metal-catalyzed, 1004, 1042–1052
nitration, 1004–1008
nucleophilic, 1004, 1027
addition-elimination mechanism, 1035–1037
elimination-addition mechanism, 1039–1042
metal-catalyzed, 1042–1052
radical, 1052–1053
side-chain oxidation, 1148–1149
 $S_{RN}1$ mechanism for, 1053–1055
thallation, 1026
Vilsmeier-Haack reaction, 1024
- Azetidinones
reduction of, 405
- Azides
acyl, isocyanates from, 947–948
alkyl, by nucleophilic substitution, 231–232
aryl, from aryl diazonium ions, 1032
nitrenes from, 944, 946
reactions with
boranes, amines from, 344
ketones, lactams from, 953
- Aziridines
azomethine ylides from, 531
from alkenes, 947
- Azo compounds
thermal elimination reactions, 593–596
- Baccatin III, multistep synthesis, 1210–1220
acyclic precursors for, 1216
fragmentation reaction in, 1210, 1215
Mukaiyama reaction in, 1218
Pyrone diels-alder reaction in, 1212
- Baeyer-Villiger oxidation, 1134–1138
- Baldwin's rules, 310–311
- Barbier reaction, 644
- Barton deoxygenation, 460–461, 961
- 9-BBN, *see* 9-borabicyclo[3.3.1]nonane
- Benzothiazoles
sulfones of in Julia reaction, 175
- Benzoxazolium salts
2-chloro in conversion of alcohols to chlorides, 221
- Benzyloxycarbonyl
amine protective group 268
- Benzyne
as intermediate in nucleophilic aromatic substitution, 1039–1042
cycloaddition reactions of, 1041–1042
ene reaction of, 1041
generation, 1039–1040
- BINAP, *see* *Bis*-(2,2'-diphenylphosphinyl)-1,1'-binaphthyl 1,1'-binaphthalene-2,2'-diol, complexes as enantioselective catalysts for
Diels-Alder reaction, 510–512
- BINOL, *see* 1,1'-binaphthalene-2,2'-diol, complexes as enantioselective catalysts for
- Biomimetic synthesis, 142
- Bis*-(4-bromo-2,6-di-*t*-butylphenoxy) methylaluminum (MABR)
catalyst for Mukaiyama aldol reaction, 84
catalyst for Diels-Alder reaction, 500
- Birch reduction, 436–439
examples, 438
- 9-borabicyclo[3.3.1]nonane, 338–339
- Borane, derivatives
alkenyl
in alkene synthesis, 797–798
palladium-catalyzed coupling, 740–741
alkynyl, addition to aldehydes, 805
allylic, 784
addition reactions with aldehydes, 797–809
t-butyl (isopinocampheyl) chloro as reducing agent, 415–416
bis-(1,2-dimethylpropyl), 338
bis-(iso-2-ethylapopinocampheyl) chloro as reducing agent, 416
bis-(isopinocampheyl)
addition reaction of *b*-allyl, 799
hydroboration by, 349–350

- Borane, derivatives (*Cont.*)
borane, *bis*-(isopinocampheyl) chloro
as reducing agent, 415–416
carbonylation of, 786–792
catechol
hydroboration by, 340–341
halo
hydroboration by, 340
homologation of using α -halo enolates, 792–793
isopinocampheyl
enantioselective ketone synthesis using,
791–792
hydroboration by, 350
pinacol
hydroboration by, 340–341
radicals from, 958–959
reactions of, 344–347
amination, 347
fragmentation, 899
halogenation, 346
oxidation, 344–345, 958–959
palladium catalyzed cross-coupling, 739–746
stereoselective synthesis of alkenes using,
793–797
synthesis from
boron halides and organometallic reagents,
784–785
cuprates, 585
thermal isomerization, 342–344
1,1,2-trimethylpropyl, 338–339
Borinate esters, 785
Borinic acids, 785
Borohydrides, alkyl
as reducing agents, 399–400, 409–411, 413,
415, 1110
Boron enolates
aldol reactions of, 71–73, 117–119
chiral, 117–119
in discodermolide synthesis, 1036
Boronate esters, 785
alkenyl, stereospecific synthesis of alkenes
using, 797
 β -allyl, enantioselective addition reactions of,
799–801
palladium-catalyzed cross-coupling, 740–743
vinyl, as dienophiles, 526
Boronic acids, 785
alkenyl
intramolecular Diels-Alder reactions, 526
palladium-catalyzed cross-coupling, 740–742
aryl
nickel-catalyzed cross-coupling, 758
Boron tribromide
ether cleavage by, 239
Boron trifluoride
ether cleavage by, 239
T-BOC, *see t*-butoxycarbonyl
BOP-Cl, *see Bis*-(2-oxo-3-oxazolidinyl) phosphinic
chloride
BOX-catalysts, *see* Copper *bis*-oxazolines
Bromides
alkenyl
synthesis by hydroboration-halogenation, 352
synthesis by
hydrozirconation-bromination, 357
alkyl, synthesis by
hydroboration-bromination, 347
oxidative decarboxylation, 1147
Bromination
alkenes, 298, 300
aromatic, 1009
Bromine azide, 306
Bromohydrins
synthesis of, 301–303
Bromonium ions
intermediates in alkene bromination, 298–300
1,3-butadiene
1-methoxy-3-trimethylsiloxy-, as diene, 487–488
t-butoxycarbonyl
amine protective group, 268
t-butyldimethylsilyl
as hydroxy protective group, 264
Cadmium, organo- compounds, 661–662
reactions with acyl chlorides, 661–662
Calcium borohydride
reducing agents, 399
Camphorsulfonamides as chiral auxiliaries for
aldol reaction, 123
Diels-Alder reactions, 502
Carbamates
lithiation of, 630
nickel-catalyzed coupling of, 757
Carbanions, *see also* Enolates
nitrile, 34, 770, 1167
phosphonate, 164–169
 α -silyl
olefination reactions of, 171–174
stabilization by functional groups, 2–4
Carbenes, as reaction intermediates, 903–941
alkenyl, cyclopropenes from, 941
cyclopropylidene, opening to allenes, 941
generation of
from diaziridines, 913
from diazo compounds, 909–913
organomercury compounds, 915–916
polyhalo methanes, 914–915
sulfonyl hydrazones, 913
insertion reactions, 934–938
examples, 939–940
intramolecular, 938
selectivity of catalyst for, 936–937
metallo-, 905, 926–929
reaction with
alkenes, 905–908, 916–934
phenyl
generation, 914–915

- singlet, 903, 906, 916
- substituent effects on, 904, 909
- triplet, 903, 906, 916
- ylides, generation by, 938, 940
- Carboalumination
 - alkenes, 354–355
 - alkynes, 356–357
 - examples, 357
- Carbocations
 - alkylation by, 862–863
 - Friedel-Crafts reaction, 1014–1017
 - as intermediates, 862–892
 - fragmentation reactions of, 897–900
 - polyene cyclization, 864–869
 - rearrangement of, 883–892
 - pinacol, 883–889
 - reduction by silanes, 425–428
- Carbocation rearrangements
 - during alkene chlorination, 301
 - during reaction of alkenes with hydrogen halides, 291
- Carbometallation reactions by
 - alkylaluminum compounds, 353–357
 - copper-magnesium reagents, 695–697
 - zirconium compounds, 356–357
- Carbonate esters
 - iodocyclization, 314, 317
 - protecting group for diols, 267
- Carbonyl compounds, *see also* Aldehydes; Esters; Ketones
 - α -halogenation, 328–331
 - [2+2]-photocycloaddition with alkenes, 548–551
 - reaction with
 - allylic silanes, 815–827
 - allylic tin compounds, 836–850
 - organomagnesium compounds, 637–644
 - phosphonium ylides, 157–164
 - phosphonate anions, 164–170
 - α -silyl carbanions, 171–174
 - sulfones anions, 174–176
 - reductive coupling of 444–452
 - examples, 451
 - mechanism, 447–448
 - reductive deoxygenation, 452–457
 - Clemmensen reduction, 452–453
 - via dithiolanes, 453–454
 - via *N*-sulfonyl hydrazones, 453
 - Wolff-Kishner reduction, 453
 - α -selenylation, 331–333
 - α -sulfonylation, 331–333
 - synthesis from
 - alkenes by hydroboration-oxidation, 345
 - γ,δ -unsaturated
 - from Claisen rearrangement, 561–564
 - from Ireland-Claisen rearrangement, 567–576
- Carbonylation reactions
 - boranes, 786–787
 - hydroformylation, 759–760
 - Fischer-Tropsch process, 760
 - palladium-catalyzed, 748–754
- Carbonyl-ene reaction, 869–881
 - computational model for, 872–873
 - enantioselective catalysts for, 874–875
 - examples, 878–879
 - intramolecular, 875–877
 - Lewis acid catalysts for, 870, 874
 - mechanism, 870–871
 - stereoselectivity of, 871, 873
 - tandem with
 - Mukaiyama reaction, 876
 - pinacol rearrangement, 886–888
 - Sakurai reaction, 877
- Carboxylic acid derivatives
 - acyl chlorides, synthesis of, 243–244
 - partial reduction of, 401–403
 - substitution reactions of, 242–256
- Carboxylic acids
 - aromatic
 - dissolving metal reduction, 439
 - synthesis by oxidation, 1148–1149
 - conversion to esters
 - using cesium salts, 227–228
 - dianions
 - alkylation of, 33–34
 - esterification of
 - by nucleophilic substitution, 227–228
 - diazo compounds, 227
 - fischer, 252
 - β -keto, decarboxylation of, 23–24
 - oxidative decarboxylation, 1145–1148
 - protective groups for
 - orthoesters, 275–276
 - oxazolines, 275
 - reactions with
 - diazomethane, 227
 - trimethylsilyldiazomethane, 227
 - reduction by
 - diborane, 400
 - synthesis from
 - alkenes by hydrocarbonylation, 749–750
 - boronic acids, 345
 - malonate esters by alkylation, 22–23
 - methyl ketones by oxidation by
 - hypochlorite, 329
 - organomagnesium compounds by
 - carbonation, 638
 - unsaturated
 - enantioselective hydrogenation of, 378–379
 - iodolactonization of, 312–316
- α,β -unsaturated
 - from amine-catalyzed condensation reactions, 147–148
- γ,δ -unsaturated
 - synthesis by orthoester Claisen rearrangement, 564–567
- Catechol borane, *see* Borane, derivatives, catechol
- Cbz, *see* benzyloxycarbonyl

- Cerium, organo- compounds
 reactions with
 amides, 666
 carboxylate salts, 666
 ketones, 664–666
- Chelation effects in
 aldol addition reactions, 109
 allyl silane addition reactions, 818–819
 allyl tin addition reactions, 838, 840
 enolate alkylation, 28–29
 enolate formation, 11–12
 ester enolates, 80, 571
 imine anions, 51–52
 ketone-organomagnesium reactions, 649
 Mukaiyama aldol reaction, 98
- Cheletropic elimination, 591–593
 bicyclo[2.2.1]hepta-2,5-dien-7-ones, 593
 sulfolene dioxides, 591–592
- Chiral auxiliaries
 for aldol reactions, 114–121
 examples, 120
 oxazolidinones as, 114–116
 oxazolidinone-2-thiones, 114–125
 thiazolidine-2-thiones, 119
 for Diels-Alder reaction, 499–504
 camphorsulfonamides as, 502
 examples, 503
 lactate esters as, 499–501
 mandelate esters as, 501
 oxazolidinones as, 501–502
 pantolactone as, 500–501
 8-phenylmenthol as, 500
 for enolate alkylation, 41–45
 examples, 43–44
 in discodermolide synthesis, 1236
 in Prelog-Djerassi lactone synthesis, 1205–1208
- Chlorination
 alkynes, 335–336
 aromatic, 1008–1014
 alkenes, 300–301
- Chloromethylation
 aromatic, 1023
- Chromium, organo-compounds
 aromatic compound, tricarbonyl complexes, 768–770
 reactions with carbanions, 770
- Chromium oxidants
 alcohols, 114
 alkenes
 allylic oxidation, 1116–117
- Claisen condensation, 149–157
- Claisen rearrangement, 560–564
 catalysis by
 Lewis acids, 562
 Pd (II) salts, 562
 examples, 563
- Clark-Eschweiler reaction, 430–431
- Clemmensen reduction, 452–453
- Collins reagent, 1053
- Combinatorial synthesis, 1252–1259
 epothilone analogs by, 1257–1259
 sample splitting method for, 1253–1254
 spirooxindoles by, 1256–1257
 structural diversity from, 1253
 tagging protocol for, 1254–1255
 Ugi multicomponent reaction in, 1256
- Concerted pericyclic reactions, definition, 473
- Conjugate addition
 allylic silanes, 830–833
 by carbon nucleophiles, 183–199
 examples, 185
 competition with 1,2-addition, 184, 189
 cyanide ion in, 198–199
 definition, 64
 enamines, 193
 enantioselective catalysts for, 195–196
 enolate equivalents for, 190–193
 examples, 194
 kinetic control of 186
 of nitroalkenes, 188, 192, 198
 organocopper compounds in, 686–694
 enantioselective, 702–703
 organocopper-zinc reagents, 694–697
 enantioselective, 703
 of organometallic reagents, 197–198, 686–695
 stereoselectivity, 188, 193–197
 sulfur ylides and enones, 178
 with tandem alkylation, 189–190, 690–691
- Convergent steps in multistep synthesis, 1163
- Cope elimination, *see* amine oxides, thermal elimination
- Cope rearrangement, 552–560
 boat versus chair transition structure for, 554–555, 557
 catalysis by Pd (II) salts, 555
 examples, 558–559
 oxy-Cope rearrangement, 556–557
 examples, 559–560
 siloxy-Cope rearrangement, 556–557
 stereochemistry of, 552–554
- Copper salts as catalysts for
 alkene photoaddition, 544–545
 aromatic substitution, 1030, 1042–1045
 aryl halide coupling, 703–705
 carbene addition, 921–922
- Copper, organo compounds, 675–706
 boranes from, 585
 catalysis in
 conjugate addition, 690–694
 cyclopropanation by diazo compounds, 924–925
 aromatic substitution, 1042–1045
 conjugate addition reactions of, 686–695
 enantioselective, 702–703
 examples, 688–689
 mechanism, 687, 700–702
 tandem alkylation, 690

- cuprates, 676
 alkenyl, 679
 cyano, 677, 679–680
 mixed, 677–680
 stannyl, addition to alkynes, 834
magnesium, mixed organometallic reagents, 695–697
mechanisms
 computational interpretation of, 697–702
 preparation of, 675–680
reactions with
 allylic acetates, 682–683
 epoxides, 685–686
 halides and sulfonates, 680–685
 unsaturated ketones and esters, 686–694
reactivity, summary, 705–706
structure of, 675–677
zinc, mixed organometallic reagent, 694–695
 conjugate addition of, 694–696
Copper *bis*-oxazolines
 as chiral catalysts for
 aldol reaction, 128
 conjugate addition, 195–196
 Diels-Alder reactions, 507
 Mannich reactions, 143
Crabtree catalyst
 homogenous hydrogenation, 375–376
Crown ethers
 catalysis of nucleophilic substitution by, 224–225
 enolate reactivity, effect on, 20
Cuprates, *see* Copper, organo- compounds
Curtius rearrangement, 947–950
 isocyanates from, 947–949
 diphenylphosphoryl azide as reagent, 948
 macrolactonization by, 948
Cyanide ion
 conjugate addition by, 198–199
Cyanoethyl as protecting group, 1251
Cyclization
 electrophilic of alkenes, 310–328
 radical, 967–973
 in reductive by SMI_2 , 448–449
Cycloaddition reactions
 1,3-dipolar, 526–538
 examples, 535
 ylides generated from carbenes, 938, 940
[2+2], 538–543
 alkenes and carbonyl compounds, 548–551
 alkenes and enones, 545–548
 alkenes and ketenes, 539–541, 543
 photocycloadditions of enones, 545–548, 1092
 zwitterionic intermediates in, 542
Cyclobutadiene
 iron tricarbonyl complex, 768
Cyclobutanes
 synthesis by [2+2] cycloaddition, 538–543
Cyclobutanones
 by ketene cycloadditions, 539–543
Cyclohexanones
 aldol reactions, 69, 73, 76–77
 alkylation, 25–26
 reduction, 407–409
Cyclopropanes
 enantioselective synthesis by cyclopropanation, 931–934
 catalysts for, 931, 933
 examples, 935
Simmons-Smith reagent for, 916–917, 919–923
 computational model of, 922–923
 enantioselective, 920
 examples, 916–917
 hydroxyl group directing effect in, 921–922
 Lewis acid catalysis of, 917
 synthesis using sulfur ylides, 177
 synthesis by carbene addition reactions, 916–934
 examples, 931–932
 synthesis by metallocarbenes, 921–927
 copper catalysts for, 924–925
 examples, 931–932
 rhodium catalysts for, 931–932
Cyclopropanones, as intermediates in Favorskii reaction, 893–895
Cyclopropenes
 from alkenyl carbenes, 941
Cyclopropylidene, ring-opening to allenes, 941
Danishefsky diene, *see* 1,3-butadiene,
 1-methoxy-3-trimethylsiloxy-
Darzens reaction, 182
Decalones, alkylation 26–27
Decarbonylation
 acyl halides, 760–761
 aldehydes, 760
 bicycle[2.2.1]heptadien-7-ones, 593
Decarboxylation
 in acylation of malonate enolates, 152
 in amine-catalyzed condensation reactions, 147–148
 of β -keto acids, 23–24
 of malonic acids, 23–24
 oxidative by
 bromine/iodosobenzene diacetate, 1147
 bromine/mercuric oxide, 1147
 lead tetraacetate, 1145–1147
 via radical intermediates, 957, 986
Dess-Martin reagent, 1072–1073
Dianions
 of dicarbonyl compounds
 alkylation, 36–37
 generation, 36
DCCI, *see* Dicyclohexylcarbodiimide
Diazaborolidines
 boron enolates from, 118–119
Diaziridines
 carbenes from, 913
Diazo compounds
 acyl, 910–911

- Diazo compounds (*Cont.*)
carbenes from, 909–913
esterification by, 227
in formation of sulfonium ylides, 583–584
ring expansion reaction with cyclic ketones,
891–892
synthesis of, 909–911
- Diazo transfer reaction, 911–912
- Diazonium ions, alkyl
rearrangement of, 890–892
- Diazonium ions, aromatic
phenyl cations from, 1028
substitution reactions of, 1027–1035
copper-catalyzed, 1032
mechanism of formation, 1028
reductive, 1029–1030
synthesis of using
azides, 1032
fluorides, 1031
halides, 1030–1032
iodides, 1031–1032
phenols, 1030
- DEAD, *see* Diethyl azodicarboxylate
- Dehalogenation
reductive, 458
- Dehydrobenzene, *see* Benzyne
- Diamines
chiral, as ligands in alkene
dihydroxylation, 1081
- DiBALH, *see* Disobutylaluminum hydride
- Diborane, *see* also hydroboration
as reducing agent, 400, 404–405
- Dicyclohexylcarbodiimide (DCCI)
acylation of alcohols, 247
acylation of amines, 253
co-reagent in dmsO oxidation, 1070
macrolactonization, 249
polypeptide synthesis, 1247
- Dieckmann condensation, 150
- Diels-Alder reaction, 474–526
alder rule, 478–480
chiral auxiliaries for, 499–504
enantioselective catalysts for, 505–518
examples, 495, 497–498, 502, 514,
521–522
FMO interpretation, 474–477
intramolecular, 518–526
bifunctional Lewis acid catalysis of, 520
copper BOX complexes in, 514
examples, 523–524
Lewis acid catalysis of, 519–520, 526
tethers for, 525–526
vinyl boronates in, 526
inverse electron demand, definition, 475
Lewis acid catalysis of, 481–487
bifunctional, 494, 519
computational model of, 482–484
copper BOX complexes, 508–510, 514
diethylaluminum chloride as, 517
examples, 496–498
LiClO₄ as, 485
MABR as, 500
Sc (O₃SCF₃)₃ as, 486
N-trimethylsilyl-*bis*-
trifluoromethanesulfonamide
as, 486
masked functionality in, 491–493
regioselectivity, 475–476
secondary orbital interactions in, 478
stereochemistry of, 474–478
steric effects in, 479–480
substituent effects on, 475–481
synthetic applications, 487–499
synthetic equivalents in, 491–493
transition structures for, 482–484
electron transfer in, 483–484
- 1,5-dienes
hydroboration in multistep synthesis, 1198
[3,3]-sigmatropic rearrangement of, 552–560
- Dienes
in Diels Alder reactions
pyridazines as, 595
pyrones as, 490–491
quinodimethanes as, 489–490, 592
1,2,4,5-tetrazines as, 595–596
1,2,4-triazines as, 595
reaction with singlet oxygen, 1124
synthesis from
alkene-alkyne metathesis, 764–765
sulfone dioxides, 591–592
- Dienophiles in Diels-Alder reactions
benzyne, 1041
nitroalkenes, 492
quinones, 494, 506–507, 512, 517
vinyl boronates, 526
vinyl dioxolanes, 493
vinyl phosphonium ions, 493
vinyl sulfones, 492
- Diethyl azodicarboxylate (DEAD)
in Mitsunobu reaction, 221
- Diimide
alkenes, reduction by, 388–390
examples, 389
- DiPCI, *see* Diisopropylcarbodiimide
- Disobutylaluminum hydride
reduction of
amides, 270
esters, 401–402
nitriles, 402–403
enones, 407
- Diisopropylcarbodiimide
in acylation of alcohols, 245
- N,N*-dimethylaminopyridine (DMAP)
as catalyst for alcohol acylation, 244
in macrolactonization, 249
- N,N*-dimethylformamide (DMF)
hydrogen atom donor in dediazonization,
1029–1030

- solvent, 18
 in hydride reduction of halide, 422
 in nucleophilic substitution, 224
N,N-dimethylpropyleneurea, as solvent, 18
 enolate reactivity, effect on, 20
 Dimethyl sulfoxide (DMSO)
 as solvent in, 18
 amine oxide elimination, 597
 bromohydrin synthesis, 301–302
 hydride reduction of halides, 422
 nucleophilic substitution, 224
 oxidation by, 1070–1072
 Dimethylsulfonium methylide, 177
 reaction with alkyl halides, 181
 Dimethylsulfoxonium methylide, 177
Vic-diols
 oxidative cleavage, 1126–1128, 1144–1145
 periodate, 1144
 lead tetraacetate, 1144–1145
 pinacol rearrangement of, 883–890
 reduction to alkenes, 450
 synthesis by
 dihydroxylation of alkenes, 1074–1075
 reductive coupling of carbonyl compounds,
 444–447
 Dioxaborolanes
 as chiral catalyst for cyclopropanation, 933
 Dioxaborolones
 chiral catalyst for aldol reaction, 126–127
 Dioxiranes, epoxidation of alkenes by,
 1097–1103, 1113
 enantioselective, 1102–1103
 substituent effects on, 1098–1100
 1,3-dioxolanes
 directing effect in cyclopropanation, 920
 as protecting groups, 266, 273
 initiation of polyene cyclization by, 865, 867
 vinyl, as dienophiles in Diels-Alder
 reactions, 493
 DIPAMP, *see* *Bis*-1,2-[(2-methoxyphenyl)
 phenylphosphino]ethane
Bis-(2,2'-diphenylphosphinyl)-1,1'-binaphthyl
 (BINAP)
 ligand in homogenous hydrogenation,
 377–378, 383
 Diphenylphosphoryl azide
 as reagent for
 amide formation, 254–255
 curtijs rearrangement, 948
 synthesis of azides, 232
 1,3-dipolar cycloadditions, 526–538
 enantioselective catalysts for, 536–538
 nickel-box complexes as, 537
 TADDOL complexes as, 537
 examples, 533–534
 FMO analysis, 529
 intramolecular, 532
 Lewis acid catalysis of, 535–538
 regioselectivity of, 528–531
 stereochemistry of, 528
 synthetic applications, 531–534
 Dipolarophiles, 527
 1,3-dipoles
 azomethine ylides as, 532
 examples, 528
 nitrile oxides as, 532
 nitrones as, 532, 535–536
 oxazolium oxides as, 530
 3-oxidopyridinium betaines as, 530
 Discodermolide, multistep synthesis, 1231–1245
 allenylstannanes in, 1235
 allylsilanes in, 1239
 boron enolates in, 1238
 chiral auxiliaries in, 1236
 scale-up of, 1243
 Disiamylborane, *see* Borane, derivatives,
bis-(1,2-dimethylpropyl)
 1,3-dithiolanes
 as carbonyl protective groups, 274
 reductive desulfurization of, 453–454
 1,3-dithianes, 274
 as carbonyl protective groups, 274
 as nucleophilic acyl equivalents, 1168
 DMAP, *see* *N,N*-dimethylaminopyridine
 DMF, *see* *N,N*-dimethylformamide
 DMPU, *see* *N,N*-dimethylpropyleneurea
 DMSO, *see* Dimethyl sulfoxide
 Double stereodifferentiation
 in aldol reactions, 108–114
 examples, 111–114
 in allylboration, 804–805
 in allylstannylation, 843–847
 DPPA, *see* Diphenylphosphoryl azide
 (Eap)₂CCl, *see* *Bis*-(iso-2-ethylapopinocampyl)
 chloro
 EE, *see* 1-ethoxyethyl
 Effective atomic number, 769
 Elimination reactions
 amine oxides, 345, 581, 598, 1088
 cheletropic, 591–593
 sulfone dioxides, 591
 esters, 600–601
 examples of, 598, 601
 β-hydroxyalkylsilanes, 171–172
 reductive, 681, 687
 selenoxides, 581–582, 598–599
 sulfoxides, 598–599, 602
 thermal, 590–604
 xanthates, 601, 603–604
 Enamines
 alkylation of, 31, 47–48
 examples, 54
 conjugate addition reactions of, 193
 [2 + 2] cycloaddition, 538, 542
 formation of, 46
 halogenation, 330
 as nucleophiles, 1, 46

- Enantioselective catalysts for
aldol reaction, 125–133
dihydroxylation of alkenes, 1074–1081
1,3-dipolar cycloaddition, 536–538
epoxidation, 1081–1091, 1102–1103
homogeneous hydrogenation, 377–387
Mukaiyama aldol reaction, 125–133
- Ene reaction, 869
of benzyne, 1041
- Enolate equivalents
in aldol reaction
in conjugate addition reactions, 190–192
- Enolates
acylation of, 150–157
examples, 151–152, 156
aldol reactions
boron enolates, 71–73
chelation effects in, 102–105
control of stereoselectivity in, 101–108
lithium enolates, 67–71
tin enolates, 73–78
titanium enolates, 73–78
zirconium enolates, 73–78
alkylation of, 21–31
enantioselective, 41–45
intramolecular, 36–40
stereoselectivity, of, 24–29, 31–33
torsional effect in, 27–28
allylation
palladium-catalyzed, 712–715
arylation
by chromium tricarbonyl complexes, 769–770
palladium-catalyzed, 728–730
boron
in aldol reactions, 71–73
chiral, 117–119
formation of, 72–73
stereochemistry of, 71–73
conjugate addition by, 183–189
composition of, table, 7–8, 12
formation of, 2–17
bases for, 4–5
chelation, affect of, 11
enantioselective, using a chiral base, 13–14
from enones by reduction, 16–17
from silyl enol ethers, 14–15, 138
kinetic versus thermodynamic control, 2–10
regioselectivity of, 5–9
stereoselectivity of, 9–12, 69–70
lactam
stereoselective alkylation, 44–45
lithium
in aldol reactions, 67–71
as nucleophiles, 1
oxidation, 1134, 1138–1142
by oxaziridines, 1141–1142
reactivity
effect of polyamines on, 21
solvent effects on, 17–21
- tin
aldol reactions of, 73–78
- titanium
aldol reactions of, 73–78
preparation of, 74–75
of α,β -unsaturated, 12
x-ray crystal structures of
zirconium
aldol reactions of, 73–78
- Enol ethers
as enolate equivalents, 82–83
 α -lithio, as acyl anion equivalents, 1167
oxidation by singlet oxygen, 1123
preparation from
esters by lombardo's reagent, 661
carbonyl compounds by wittig reaction,
162–163
- Enones, *see* ketones, α,β -unsaturated
- Ephedrine
chiral auxiliary in aldol reactions, 116–117
- Epithilone a, multistep synthesis, 1220–1231
alkyne metathesis in, 1225
macrocyclization by aldol addition, 1224
macrolactonization in, 1221
nitrile oxide cycloaddition in, 1128
olefin metathesis in, 122
- Epoxidation, 1081–1103
alkenes
computational model, 1098
by dioxiranes, 1098–1103
enantioselective by manganese diimines,
1088–1089
by hydrogen peroxide, 1097
hydroxy directing effect, 1093, 1095, 1099
by peroxycarboxylic acids, 1091–1096
by peroxyimide acids, 1095–1096
torsional effect on, 1093
allylic alcohols, 1082–1088
computational model, 1083–1088
mechanism, 1082–1083
sharpless asymmetric, 1082
stereoselectivity, 1085–1086
tartrate ligands for, 1082
- Epoxides
acetoxo, rearrangement to acetoxo ketones,
1112–1113
reactions
organocopper compounds, 685–686
rearrangement to carbonyl compounds,
1111–1112
catalysts for, 1111–1112
reduction by
diborane, 1110
DiBAIH, 1110
LiAlH₄, 424, 1109–1110
lithium triethylborohydride, 1110
ring opening, 1104–1109
base-catalyzed, 1114–1116
Lewis acid catalysts for, 1111

- silyl, rearrangement, 1114
synthesis, *see also* Epoxidation
 by Darzens reaction, 182
 from ketones and sulfur ylides, 177–179
 2-trimethylsilyl, synthesis, 182
Eschenmoser's salt, 140
Esters
 allylic
 copper-catalyzed coupling
 palladium catalyzed carbonylation, 751
 reaction with carbocations, 863
 allyloxycarbonyl, as protective groups for
 alcohols, 266
 benzoate
 by oxidation of ethers, 1069
 boron enolates of, 80–81
 condensation reactions of, 149–150
 dealkylation by trimethylsilyl iodide, 240
 α -diazo
 synthesis, 912
 enolates of, 79, 568
 chelation effects in, 571–572
 conjugate addition reactions, 186–188, 190
 intramolecular alkylation, 36
 zinc, 657–659
 as hydroxy protective groups
 allyloxycarbonyl, 266
 trichloroethoxycarbonyl, 265
 lithium enolates of
 aldol reactions of, 78–81
 alkylation, 31–33
 formation of, 78–81
 chelation in, 32–33, 80
 silyl ketene acetals from, 79
 partial reduction of, 401–403
 β -sulfonyl
 palladium-catalyzed allylation of, 714
 synthesis from
 aldehydes, 1131
 boranes by halo enolate homologation,
 792–793
 carboxylic acids, 227–228, 252
 α -diazo ketones, by Wolff rearrangement,
 941–946
 ketones by Baeyer-Villiger oxidation,
 1134–1139
 thermal elimination reactions of, 601–603
 α,β -unsaturated
 conjugate addition by organocopper
 compounds, 686–695
 synthesis by Wadsworth-Emmons reaction,
 164–166
Ethers
 allyl
 [2,3]-sigmatropic rearrangement of anions,
 587–588
 allyl vinyl
 Claisen rearrangement, 561–564
 formation, 561–562
 aromatic
 dissolving metal reduction, 436
 aryl vinyl
 Claisen rearrangement of, 564
 benzyl
 hydrogenolysis, 394, 396
 cleavage of, 239–240
 cyclic
 formation by oxymercuration, 325–326
 halo, by halocyclization, 311, 317–318
 oxidation
 by ruthenium tetroxide, 1069
 protective groups for alcohols
 allyl, 264
 benzyl, 262–263
 t-butyl, 262
 dimethoxybenzyl, 263
 2,4-dimethoxytriphenylmethyl, 262
 synthesis from
 alcohols, 227
 alkenes by addition of alcohols, 294
 ketones and silyl ethers, 427–428
 1-ethoxyethyl
 as hydroxy protective group, 260
Favorskii rearrangement, 892–895
 mechanism, 894–895
Felkin model
 aldol reaction, 90–91
 ketone reduction, 410–411
Ferrocene, 768
Fischer esterification, 252
Fischer-Tropsch process, 760
Fluoride ion
 as base in conjugate addition, 184
 in allyl silane additions, 826, 832–833
Fluorination
 alkenes, 303–304
 ketones, 331
Formamidines
 lithiation of, 630
Formylation
 aromatic, 1024
Fragmentation reactions
 carbocations, 897–900
 in Baccatin III synthesis, 1211–1219
 in longifolene synthesis, 1191
 radicals, 984–985
 reductive, 461
Free radicals, *see* Radicals
Friedel-Crafts acylation, 1017–1023
 catalyst for, 1017
 examples, 1022–1023
 intramolecular, 1016–1020
 mechanism, 1019
Friedel-Crafts alkylation reaction, 1014–1017
 by benzyl cations, 425
 examples, 1017

- Friedel-Crafts alkylation reaction (*Cont.*)
 intramolecular, 1016–1017
 Lewis acid catalysts for, 1008–1010
 rearrangement during, 1014–1015
 scandium triflate catalysis, 1017
Fries rearrangement, 1023

 stereoselectivity of, 370–372
 homogeneous catalysis of, 374–376
 α -amido acrylic acids, 380, 384
 computational model for, 380–382
 Crabtree catalyst in, 375–377
 enantioselective, 376–387
 examples, 376, 384–385
 styrene derivatives, 386–387
 Wilkinson's catalyst in, 374
 ketones
 enantioselective, 391–395

- Hydrogen halides
 addition to alkenes, 290–293
 addition to alkynes, 333–337
- Hydrogenolysis
 benzyl ethers, 394, 396
- N*-hydroxysuccinimide in amide synthesis,
 253–254, 1248
- Hydrozirconation, 356–358
- Hypophosphorous acid
 as hydrogen atom donor in reduction, 432, 460
 in reductive dediazonization, 1029
- Imidazole
N-acyl
 acylation of alcohols by, 246–247, 265
 enolate acylation, 154
- Imidazolidines
 catalysts for
 enolate arylation, 730
 olefin metathesis, 761
- Imidazolyl disulfide
 macrolactonization by, 249
- Imides
N-acyliminium ions from, 145
- Imine anions, 48–52
 alkylation of, 50–52
 enantioselective, 51–52
 as nucleophiles, 1
- Imines, reactions with
 silyl enol ethers, 142–143
 silyl ketene acetals, 145
 zincate reagents, 659
- Iminium ions
n-acyl
 addition reactions of, 195–196, 828
 formation of, 195–196
 intermediates in
 Mannich reactions, 140–143
 Knoevenagel reactions, 147–148
 reactions with
 allylic silanes, 828–829
 organozinc compounds, 652
- Indium, organo- compounds
 from allylic halides, 663–664
- Indium trichloride
 catalyst for Mukaiyama aldol reaction, 84
- Indole
 palladium-catalyzed arylation, 1045
- Iodination, aromatic, 1013
- Iodine azide, 305
- Iodine atom transfer, 970, 972
- Iodine isocyanate, 305
- Iodine nitrate, 305
- Iodine thiocyanate, 305
- Iodobenzene diacetate, oxidation of amides, 950
- Iodolactonization, 312–316
 examples, 315–316
- (*Ip*c)₂BCl, *see* Borane, *bis*-(isopinocampheyl)
 chloro
- Ip*cBH₂, *see* Borane, isopinocampheyl
- (*Ip*c)₂BH, *see* Borane, *bis*-(isopinocampheyl)
- Ireland-Claisen rearrangement, 567–576
 boat versus chair transition structure, 569–570
 chelation effects in, 571–572
 enantioselective catalysts for, 572–573
 examples, 574–575
 Lewis acid catalysis, 572
 stereochemistry of, 567–571
- Iron, organo- compounds
 cyclobutadiene tricarbonyl complex, 769
 ferrocene, 768
- Isocyanates, synthesis from
 acyl azides, 947–948
N-bromo amides, 949
- Jones reagent, 1065
- Julia olefination reaction, 174–176
 examples, 176
 Julia-Kocienski reaction, 174
 Julia-Lythgoe reaction, 174
- Juvabione, multistep syntheses of, 1174–1186
 diastereoselective from cyclohexenone,
 1179–1180
 enantioselective, 1182–1185
 from aromatic starting materials, 1175–1176
 from terpene starting materials, 1176–1181
 [2,3]-sigmatropic rearrangement in, 1183
 stereocontrolled, 1180–1181
- Ketenes
 [2+2]cycloaddition reactions with alkenes,
 539–541
 examples, 543
 intramolecular, 540–541
 intermediates in Wolff rearrangement, 941–943
- B*-ketoesters
 alkylation of, 22–24
- Ketones
 α-acetoxy
 from acetoxy epoxides, 1112–1113
 from enol ethers, 1133
 from silyl enol ethers, 1133–1134
 reduction of, 441–442
 aldol reactions of, 65–78
 α-alkoxy
 aldol reactions of, 92, 109
 reactions with organometallic compounds, 650
 reduction by hydride donors, 411, 413
 β-alkoxy from Mukaiyama reactions, 86–87
 examples, 88
 alkylation of, 24–31
 examples, 29–30
 β-amino
 preparation by Mannich reaction, 140–141

Ketones (*Cont.*)

- aryl
 - reduction by silanes, 427
 - synthesis by Friedel-Crafts acylation, 1017–1023
 - carboxylation of, 154
 - cyclic
 - ring expansion with diazo compounds, 891–893
 - stereoselective reduction of, 407–410
 - synthesis by hydrocarbonylation, 749
 - α -diazo
 - esters from by Wolff rearrangement, 941–944
 - metal carbenes from, 926–930
 - synthesis, 910–912
 - enolates
 - acylation of, 155–156
 - aldol reactions, 67–71
 - alkylation of, 24–31
 - oxidation by oxaziridines, 1141
 - fluorination, 331
 - α -halo
 - Favorskii rearrangement of, 892–895
 - reactions with organoboranes, 792
 - α -halogenation, 328–331
 - hydrogenation
 - enantioselective, 391–395
 - α -hydroxymethylene derivatives, 155
 - methyl
 - oxidation by hypochlorite, 329
 - α -oxy
 - reductive deoxygenation, 441–443
 - organocerium compounds, reaction with, 665–666
 - organomagnesium compounds, reactions with
 - alcohols from, 637–638
 - chelation effect in, 649
 - enantioselective catalyst for, 649
 - enolization during, 642
 - reduction during, 642
 - stereochemistry of, 648
 - oxidation, 1131–1143
 - Baeyer-Villiger, 1134–1138
 - dicarboxylic acids from cyclic, 1131
 - oxaziridines, 1141
 - selenium dioxide, 1143
 - reaction with
 - azides, lactams from, 951
 - hydrazoic acid, amides from, 950
 - reduction of, 407–415
 - enantioselective, 415–421
 - chelation control in, 411–415
 - synthesis from
 - acyl chlorides, 637, 657, 662–663, 739–743
 - alcohols by oxidation, 1063–1074
 - alkenes by hydroboration-oxidation, 345
 - alkenes by Pd-catalyzed oxidation, 709–712
 - alkynes by mercury-catalyzed hydration, 335–6
 - boranes, 787–792
 - carboxylate salts and organolithium compounds, 644–645
 - carboxylic acid derivatives by Pd-catalyzed coupling, 736, 743, 747–748
 - epoxides by rearrangement, 1111–1114
 - hydrazones by alkylation, 52–53
 - imines by alkylation, 51–54
 - β -keto esters by alkylation, 23–24
 - N*-methoxy-*N*-methyl carboxamides and organolithium compounds, 638
 - nitriles and organomagnesium compounds, 637
 - organotin compounds by Pd-catalyzed carbonylation, 752
 - pyridine-2-thiol esters and organomagnesium compounds, 638
 - α,β -unsaturated
 - conjugate addition reactions of, 184, 189, 686–696, 830–833
 - enolates of, 12, 30–31
 - from Mannich bases, 140–142
 - organocopper addition, 686–696
 - photocycloaddition reactions, 544–549
 - reduction by lithium metal, 436
 - synthesis from
 - alkenyl mercury compounds, 663
 - silanes, 828–829
 - stannanes, 754
 - 1,2- versus 1,4-reduction, 406–407, 419
 - β,γ -unsaturated
 - from acylation of allyl silanes, 829
 - γ,δ -unsaturated
 - from Claisen rearrangement, 561–564
 - zinc enolates, reaction with, 657–660
- Khmds, *see* Potassium hexamethyldisilazide
- Knoevenagel reactions, 147–148
- decarboxylation during, 147
 - examples, 148
- K-Selectride®, *see* potassium *tris*-(1-methylpropyl) borohydride
- Lactate esters as chiral auxiliaries for Diels-Alder reaction, 499–501
- Lactones
 - dithiolane derivatives of, 276
 - iodo, by iodolactonization, 312–316
 - α -methylene, synthesis of, 142
 - partial reduction by DiBAIH, 401
 - synthesis
 - from ethers by oxidation, 1069
 - macrocyclic, 248–249
- Lanthanide, organo- compounds, 664–666
- Lanthanide salts
 - alkoxides, as hydride transfer catalysts, 429
 - as catalysts for
 - aromatic nitration, 1004
 - carbonyl ene reaction, 874–875

- Fries rearrangement, 1023
 Mukaiyama aldol reaction, 82
 LDA, *see* lithium di-isopropylamide
 Lead tetraacetate as oxidant
 amide oxidation, 949
 diol cleavage, 1144–1145
 oxidative decarboxylation, 1145–1148
 Lewis acid catalysis in
 alcohol acylation, 245–246
 carbonyl ene reaction, 869, 874
 Claisen rearrangement, 562
 conjugate addition of allylic silanes, 830–831
 control of stereochemistry in aldol reaction, 119–125
 Diels-Alder reactions, 481–487
 1,3-dipolar cycloaddition, 535–538
 epoxide ring opening, 1106
 Friedel-Crafts acylation, 1017
 Friedel-Crafts alkylation, 1014–1017
 hydrosilation, 809–811
 Mukaiyama aldol reaction, 82–88, 93–95
 organocopper reactions, 702
 organotin reactions with carbonyl compounds, 837–838
 rearrangement of epoxides to carbonyl compounds, 1111–1112
 Linear sequence in multistep syntheses, 1163
 Lithium aluminum hydride
 as reducing agent, 396–399
 for alkyl halides, 425
 for epoxides, 424
 Lithium borohydride
 as reducing agent, 399
 Lithium di-isopropylamide
 base for enolate formation, 5, 31
 Lithium hexamethyldisilazide (LiHMDS)
 base for enolate formation, 5
 Lithium tetramethylpiperidine (LiTMP)
 base for enolate formation, 4, 69–70
 Lithium *b*-isopinocampheyl-9-borabicyclo[3.3.1]nonane hydride
 as enantioselective reducing agent, 415
 Lithium, organo- compounds
 alkenyl, from sulfonylhydrazones, 454–456
 preparation of, 624–634
 by halogen-metal exchange, 632–633
 by lithiation, 627–633
 from sulfides, 625
 reactions with
 carbonyl compounds, 637–645
 carboxylate salts, 648
 halides, 634–637
 N-methoxy-*N*-methyl carboxamides, 638
 α,β -unsaturated ketones, 644
 structure of, 626
 synthesis using, 619–620, 644–648
 examples, 646–647
 Lithium *tris*-(1,2-dimethylpropyl) borohydride
 as reducing agent, 399–400
 Lithium *tris*-(1-methylpropyl) borohydride
 as reducing agent, 399–400
 Lombardo reagent, 661
 Longifolene, multistep synthesis, 1186–1196
 carbocation cyclization in, 1193
 enone photocycloaddition in, 1192
 fragmentation reaction in, 1189
 from Wieland-Miesher ketone, 1187–1190
 L-Selectride®, *see* lithium *tris*-(1-methylpropyl) borohydride
 LS-Selectride®, *see* lithium *tris*-(1,2-dimethylpropyl) borohydride
 Luche reagent, 406, 410

 MABR, *see* *bis*-(4-bromo-2,6-di-*t*-butylphenoxy) methylaluminum
 Macrocyclization by
 aldol addition in epothilone A synthesis, 1224
 alkene acylation, 881
 Curtius Rearrangement, 948
 Dieckmann condensation, 149
 nickel-catalyzed coupling of allylic halides, 755
 olefin metathesis, 761
 palladium-catalyzed
 alkylation, 713
 cross-coupling of stannanes, 733–737
 reductive coupling of carbonyl compounds, 444
 Wadsworth-Emmons reaction, 166
 Macrolactonization
 by DCCI and DMAP, 249
 by 2-imidazolyl disulfide, 248
 by 2-pyridyl disulfide, 248
 by Yamaguchi method, 249
 in epothilone A synthesis, 1121
 Magnesium, organo- compounds
 copper-catalyzed conjugate addition of, 690–694
 examples, 693
 mechanism, 693
 cross-coupling
 cobalt-catalyzed, 761
 nickel-catalyzed, 756–758
 palladium-catalyzed, 724–728
 preparation of, 620–623
 reaction, 634–644
 acyl chlorides, 637–638
 carbon dioxide, 638
 carbonyl compounds, 637–444
 esters, 637
 formamides, 638
 halides, 636
 ketones, chelation effects in, 649
 ketones, enantioselective catalysts for, 649
 ketones, reduction during, 642
 ketones, stereochemistry of, 648
 N-methoxy-*N*-methyl carboxamides, 638
 nitriles, 637

- Magnesium, organo- compounds (*Cont.*)
 pyridine-2-thiol esters, 638
 sulfonates, 636–637
 triethyl orthoformate, 638
 structure and composition, 623–624
 synthesis using, 619–620, 634–644
 examples, 638–640
 γ,δ -unsaturated, rearrangement of, 644
- Malonate esters
 allylation, Pd-catalyzed, 712–714
 alkylation of, 22–24
 magnesium enolates of
 acylation, 152, 154
- Malonic acids
 amine-catalyzed condensation reactions or,
 147–148
 decarboxylation of, 23–24
- Mandelate esters as chiral auxiliaries for
 Diels-Alder reaction, 501
- Manganese dioxide, as oxidant, 1068
- Mannich reaction, 140–145
 enantioselective, 143–145
 examples, 141
- Markovnikov's rule, 290
- Meerwein-Ponndorf-Verley reduction, 429
- N*-methylpyrrolidinone
 as solvent, 18
- Mem, *see* 2-methoxyethylmethyl
- Mercuration
 aromatic, 1026
 electrophilic, cyclization by, 324–328
 initiation of polyenes cyclization by, 865
- Mercury, organo- compounds
 carbenes from, 916, 930
 cyclopropanation by, 930
 preparation
 from boranes, 652
 by oxymercuration, 294–298
 radicals from, 959
 reaction with
 acyl chlorides, 663
 reduction by NaBH_4 , 295
 reduction by Bu_3SnH , 319
- Metallocarbenes, *see* carbenes, metallo-
- Methane
 polyhalo
 carbenes from, 914
- 2-methoxyethoxymethyl
 hydroxy protective group, 260
- Methoxymethyl
 hydroxyl protective group, 260
- Bis*-1,2-[(2-methoxyphenyl)
 phenylphosphino]ethane
 ligand in enantioselective hydrogenation, 380
- 2-methoxypropyl
 hydroxy protective group, 259–260
- Methylthiomethyl
 hydroxy protective group, 260–261
- Michael reaction, *see* conjugate addition
- Michaelis-Arbuzov reaction, 233
- Mitsunobu reaction
 conversion of alcohols to iodides, 220–221
 glycosylation by, 231
 inversion of alcohol configuration by, 228
 phosphite esters, synthesis by, 228
 sulfonamide, synthesis by, 230
 sulfonate esters, synthesis by, 228
- MOM, *see* methoxymethyl
- MOP, *see* 2-methoxypropyl
- MTM, *see* methylthiomethyl
- Mukaiyama aldol reaction, 82–88
 chelation effects in, 100–101
 examples, 87–88
 stereoselectivity, of, 96–101
- Mukaiyama-Michael reaction, 190–193
 in Baccatin III synthesis, 1218
 in juvabione synthesis, 1181
- Multistep synthesis
 Baccatin III, 1210–1220
 control of stereochemistry in, 1171–1173
 convergent steps in, 1163
 epothilone A, 1220–1231
 juvabione, 1174–1186
 longifolene, 1186–1196
 Prelog-Djerassi lactone, 1196–1209
 protecting groups in, 1163
 retrosynthetic analysis in, 1164–1166
 synthetic equivalents in 1163, 1166–1171
- NB-enantride, *see* borohydrides, alkyl
- Nickel, organo- compounds, 754–759
 allyl complexes, 754, 768
 coupling of allylic halides, 754, 755
 coupling of aryl halides, 756
 cross-coupling of organometallic reagents, 758
- Nitration, aromatic, 1004–1008
 acetyl nitrate for, 1005
 examples, 1006–1009
 lanthanide catalysis of, 1005–1006
 nitrogen dioxide and ozone for, 1006–1008
 transfer, 1006–1008
 trifluoroacetyl nitrate for, 1005
- Nitrenes, 944–947
 generation from azides, 944
 reactions, 946–947
 singlet, 944
 triplet, 944
- Nitrile oxides
 dipolar cycloaddition, 535–538
 in epothilone A synthesis, 1229–1230
- Nitriles
 carbanions from, 65
 α -alkoxy, as nucleophilic acyl
 equivalents, 1168
 alkylation, 34
 reaction with chromium tricarbonyl
 complexes, 769–770

- conversion to primary amides, 256, 404
- partial reduction by DiBAIH, 402–403
- reaction with
 - organomagnesium compounds, 634
- synthesis by
 - metal-catalyzed substitution, 52
 - nucleophilic substitution, 223–225
- Nitrite esters, alkoxy radicals from, 991–992
- Nitroalkanes
 - nucleophiles in amine-catalyzed condensation, 147
- Nitroalkenes
 - conjugate addition reactions of, 188, 193, 198–199
 - dienophiles in Diels-Alder reactions, 494
- Nitrones, dipolar cycloaddition of, 535–538
- N*-nitroso anilides
 - aryl radicals from, 1053
- Nitrosyl chloride, 306
- Nitrosyl formate, 306
- NMP, *see n*-methylpyrrolidinone
- Normant reagents, *see* copper, organo-
- N-Selectride®, *see* sodium *tris*-(1-methylpropyl) borohydride
- Nucleophilic aromatic substitution, 1027–1041
 - addition-elimination mechanism, 1035–1037
 - elimination-addition mechanism, 1039–1041
 - metal-catalyzed, 1042–1052
 - copper, 1042–1045
 - examples, 1052
 - palladium, 1045–1052
 - pyridine derivatives, 1037
- Nucleophilic substitution at substituted carbon
 - catalysis by crown ethers, 224–227
 - phase transfer catalysis in, 224–225
 - solvent effects on, 224–225
 - synthetic applications, 215–233
 - azides, 231–232
 - esters, 226–229
 - ethers, 226–227
 - examples of, 234–238
 - nitriles, 225–226
 - phosphite esters, 228, 233
 - phosphonate esters, 233
 - phosphonium salts, 225
 - sulfides, 233
 - sulfonate esters, 228
- Olefinations reactions
 - examples of generalized aldol reaction, 66, 155
 - Julia, 174–176
 - Peterson reaction, 171–174
 - Wadsworth-emmons reaction, 164–170
 - Wittig Reaction, 157–164
 - examples, 159–164
- Olefin metathesis, 761–766
 - catalysts for, 762, 763, 765
 - examples, 765, 766
 - in epothilone A synthesis, 1222
 - in Prelog-Djerassi lactone synthesis, 847
 - mechanism, 764
- Oligonucleotides, solid phase synthesis, 1245–1249
 - phosphoramidite method for, 1251
 - protecting groups in, 1251
- Oppenauer oxidation, 429
- Orthoester
 - carboxylic acid protecting group, 275–276
 - Claisen rearrangement, 564–567
 - reaction with organomagnesium compounds, 634
- Osmium tetroxide
 - dihydroxylation of alkenes, 1074–1077, 1080
 - computational model for, 1078–1079
 - co-oxidants for, 1076
 - enantioselective, 1076–1078
 - examples, 1079
- Oxalate esters
 - acylation of enolates by, 150–155
- Oxalyl chloride
 - Swern oxidation, 1070
 - synthesis of acyl chlorides, 243
- Oxaphosphetane
 - intermediate in Wittig reaction, 157–164
- Oxazaborolidines
 - chiral catalysts for aldol reactions, 126–128
 - chiral catalysts for ketone reduction, 416–418
 - computation model of, 418–419
- Oxaziridines
 - oxidation of enolates by, 1138–1142
 - in synthesis of Baccatin III, 1211–1219
 - in synthesis of discodermolide, 1233, 1236, 1241
- Oxazolidinones, as chiral auxiliaries for
 - aldol reactions, 114–116
 - Diels-Alder reaction, 499–505
 - enolate alkylation, 36–42
 - palladium-catalyzed enolate arylation, 728
 - reactions with *n*-acyliminium ions, 145, 146
- Oxazolidine-2-thiones
 - chiral auxiliaries in aldol reactions, 126–128
- Oxetanes
 - from [2+2]-photocycloaddition of alkenes and carbonyl compounds, 544–548
- Oxidation of
 - alcohols, 1063–1074
 - allylic alcohols, 1082–1088–1089
 - computational model 1083–1087
 - mechanism, 1082–1083
 - sharpless asymmetric, 1082
 - stereoselectivity, 1082, 1085, 1087
 - tartrate ligands for, 1082, 1084
 - alkenes
 - allylic, 1116–1119
 - dihydroxylation, 1074–1081
 - benzylic, 1148–1149
 - enolates, 1138–1142
 - by oxaziridines, 1141–1142
 - hydrocarbons, 1148–1150

- Oxidation of (*Cont.*)
ketones, 1131–1143
Baeyer-Villiger, 1134–1139
Oxime ethers, in radical cyclizations, 973, 974, 979–981
Oximes
amides from, by Beckmann rearrangement, 951–955
fragmentation of, 952
Bis-(2-oxo-3-oxazolidinyl) phosphinic chloride
Amide synthesis by, 253
Oxy-cope rearrangement, 553, 556–559
anionic, 556–559
in synthesis of juvabione, 1183
examples, 557–559
Oxygen, singlet
alkene oxidation by, 1117–1126
examples, 1121
in zeolite, 1120, 1121
mechanism, 1119, 1121
regioselectivity, 1126
generation, 1118
reaction with
enaminoketones, 1124
enol ethers, 1122
Oxymercuration, 293–298
alcohols from, 295–298
computation model of, 297–298
cyclization by, 324–327
ethers from, 297–298
examples, 298
stereochemistry of, 295–297
Ozonolysis
alkenes, 1129–1131
examples, 1131

Palladacycle
as catalyst in Heck reaction, 715–723
Palladium, organo-, intermediates, 706–754
acylation of
organotin compounds, 833, 839
 π -allyl, 369, 707, 712, 713, 751, 754
nucleophilic substitution of, 712–715
alkene oxidation, 709–712
mechanism, 709
alkene arylation, 715–719
mechanism, 716–717
 β -elimination reactions of, 707, 709, 712, 716, 717, 723
carbonylation reactions of, 708, 748–752
catalysis of aromatic substitution, 1042–1052
mechanism, 1046–1047
cross-coupling reactions of, 708, 723–739
enol sulfonate esters, 730
boron compounds, 739–746
organometallic reagents, 723–728
organotin reagents, 731–738
Heck reaction, 715–723
hydrocarbonylation, 749–750
oxidative cyclization, 711–712
solvocarbonylation, 749–750
Pantolactone as chiral auxiliaries for
Diels-Alder reaction, 599–504
Paterno-buchi reaction, 548–552
PCC, *see* chromium oxidants
PDC, *see* chromium oxidants
Peroxycarboxylic acids
alkene epoxidation, 1091–1096
Baeyer-Villiger reaction, 1136–1138
Peterson reaction, 171–174
examples, 173–174
Phase transfer catalysis
in nucleophilic substitution, 224–226
Phosphate esters
allylic
palladium-catalyzed carbonylation, 753
reductive cleavage, 439–440
Phosphines
as ligands in
enantioselective hydrogenation, 376–384
enolate arylation, 728–730
Heck reaction, 715
palladium-catalyzed aromatic substitution, 1045–1046, 1048–1049
palladium-catalyzed cross-coupling, 739, 783
Phosphite esters
synthesis by Mitsunobu reaction, 228
Phosphonate esters
in wadsworth-emmons reaction, 164–170
Phosphonium ions
alkoxy, as intermediates in nucleophilic substitution, 219–221
vinyl, as dienophiles in Diels-Alder reaction, 494
Phosphonium ylides
in Wittig reaction, 157–164
stabilized, 159
Phosphorus tribromide
reaction with alcohols, 218–221
Photochemical cycloaddition reactions, 544–551
alkene photodimerization, 544–545
copper triflate catalysis of, 544–545
enones, 545–549
in synthesis of longifolene, 1086
Phthalimides
as amine protective group, 269
in Gabriel amine synthesis, 229–230
Pinacol borane, *see* borane, pinacol
Pinacol rearrangement, 883–889
examples, 888
of epoxides, 886
stereochemistry of, 884–886
sulfonate esters in, 884–886
tandem with carbonyl-ene reaction, 886–887

- pK values
table of, 3
- Polar substituent effects
in aldol reactions, 96, 105–106
- Polyamines
enolate reactivity, effect on, 20–21
- Polyene cyclization, 864–869
examples, 868
of squalene in steroid biosynthesis, 867
- Polyenes
preparation by Pd-catalyzed cross-coupling, 733
- Polypeptide synthesis
cyclic, 1243–1245
solid phase, 1246–1250
coupling reagents for, 1248–1250
Fmoc protocol for, 1247–1248
linker groups for, 1248
t-Boc protocol for, 1246
- Potassium hexamethyldisilazide (KHMDs)
base for enolate formation, 5
- Potassium *tris*-(1-methylpropyl) borohydride
as reducing agent, 399–400
- Prelog-Djerassi lactone, multistep synthesis of, 1196–1209
chiral auxiliaries in, 1205–1207
1,5-diene hydroboration in, 1198
enzymatic desymmetrization in, 1200, 1202
from carbohydrates, 1202–1203
from meso-3,4-dimethylglutaric acid derivatives, 1199–1202
using enantioselective catalysis, 1207–1208
- Proline
enantioselective catalysis of aldol reaction, 131–133
enantioselective catalysis of Mannich reaction, 142–143
enantioselective catalysis of robinson annulation, 138–139
- Protective groups, 258–276, 1163, 1166
alcohols, 258–265
amides, 271
amines, 267–272
carbonyl compounds, 274–275
carboxylic acids, 274–275
- Pseudoephedrine
chiral auxiliary in aldol reaction, 114–116
chiral auxiliary in enolate alkylation, 42
- Pyridazines, as Diels-Alder, dienes, 595
- Pyridine derivatives
nucleophilic aromatic substitution in, 1037
- Pyridine-2-thiol esters
acylation of alcohols by, 243
- 2-pyridyl disulfide
macroloactonization by, 249
- Pyrones
as dienes in Diels-Alder reactions, 490–491, 1041
in synthesis of Baccatin III, 1212
- Quinodimethanes
as dienes in Diels-Alder reaction, 489–490, 501
- Quinones
as dienophiles in Diels-Alder reaction, 494, 506–507, 512, 517
- Radicals
addition to alkenes, 956, 959–966
by allylic silanes, 961, 965–966
by allylic stannanes, 963, 964, 965–966
examples, 963–966
mechanism, 960–961
substituent effects, 960–962
addition to carbon-nitrogen double bonds, 973
alkoxyl, generation from nitrites, 990
aryl
addition to alkenes, 1035
aromatic substitution by, 1052
from *N*-nitroso anilides, 1053
as reaction intermediates, 956–992
cyclization of, 967–990
ring size effects, 967–969
tandem with alkylation, 979–981
1,4-di- as intermediates in
photocycloaddition, 548
fragmentation of, 984–988
alkoxyl, 988–986, 992
cyclopropylmethyl, 986, 987
generation from, 959, 961
boranes, 958–959
 α -cyano acids, 962
N-hydroxypyridine-2-thiones, 957–958
 β -keto acids, 962
malonic acids, 962
organomercury compounds, 959, 961–962
selenides, 958, 961, 963, 975
thiono esters, 961, 963, 978
xanthates, 965, 972
hexenyl, cyclization, 295, 423, 569, 621–622
hydrogen abstraction, 957, 960
intramolecular, 989–991
silanes, 961
stannanes, 961, 963
iodine atom transfer, 970, 972, 974
rearrangement of, 984, 985–986
substituent effects on, 960–962
- Ramberg-Backlund reaction, 895–898
- RAMP, *see*

monomeric and dimeric copper-carbene complexes with diimine ligand, 921, 922
tetrakis-P,P,P',P'-(4-methylphenyl)-1,1'-binaphthylidiphosphine-1,2-diphenyl-1,2-ethaneamine ruthenium borohydride catalyst, 393
phenyllithium tetrameric diethyl ether complex, 626
scandium (*S, S*) phenylpyBOX trifluoromethanesulfonate hydrate, 510
tin tetrachloride complex of 2-benzyloxy-3-pentanone, 93
titanium tetrachloride complex of *O*-acryloyl ethyl lactate, 482
zinc enolate from *t*-butyl bromoacetate, 658
- Yamaguchi method for macrolactonization, 249
- Ylides
ammonium, [2,3]-sigmatropic rearrangement of, 583–585
carbonyl
from carbenes, 936–941
phosphonium in wittig reaction, 157–164
 β -oxido in wittig reactions, 162
sulfur
reactions with carbonyl compounds, 177–180
[2,3]-sigmatropic rearrangement of, 581–598
- Zinc, organo- reagents, 650–661
conjugate addition of, 198
cross-coupling
cobalt-catalyzed, 761
palladium-catalyzed, 723–729
zinc-catalyzed, 756–758
halomethyl, as carbene precursors, 916
preparation of, 650–652
from boranes, 652
reactions with, 651–655
aldehydes, 653–656
zincate reagents, 659–660
- Zinc borohydride
as reducing agent, 399
in reductive amination, 403, 404
in reduction of α -hydroxyketones, 412
- Zirconium
enolates in aldol reactions, 76–78
hydrozirconation, 355–357

Color Plate Section
